Tocilizumab	8 mg/kg IV monthly	IL-6 receptor inhibitor	Third line	Infections, leukopenia, hypercholesterolemia, hepatotoxicity
Satralizumab	120 mg subQ at weeks 0, 2, and 4, then every 4 wk	IL-6 monoclonal antibody	Recently approved	Injection site reactions, infections, headache
Inebilizumab	Two doses 300 mg IV in 2 wk apart, then 300 mg IV every 6 mo	Anti-CD19 monoclonal antibody; B cell depletion	Recently approved	Infections, leukopenia, hepatitis B reactivation, PML

Abbreviations: IL-6, interleukin 6; IV, intravenous; PML, progressive multifocal leukoencephalopathy.

is elevated in NMOSD and enhances AQP4-IgG secretion by promoting plasmablast survival. Two recently completed clinical trials of a modified version of tocilizumab, an IL-6 receptor inhibitor that is modified to extend its action compared to its parent compound, tocilizumab, showed greater than 70% suppression of attacks in AQP4-IgG–seropositive cases, although it did not show convincing evidence of benefit in NMOSD patients seronegative for AQP4-IgG.

Satralizumab, became the third regulator-approved treatment for prevention of attacks of AQP4-IgG seropositive NMOSD in August, 2020 (United States). Satralizumab is associated with risk of injection related reactions, neutropenia, infections, including opportunistic infection, and liver function abnormalities. LEVEL 1.[5]

The choice of treatment depends on availability, cost, comorbidities, side effects, and patient preference. Individualization based on efficacy indicators is not currently possible. However, available data suggest that anti-CD19 monoclonal antibody and IL-6 inhibition may be less effective in treating AQP4-IgG–seronegative than AQP4-IgG–seropositive patients in the phase 3 clinical trials and all regulator-approved treatments are indicated only for patients who are seropositive for AQP4-IgG.

In the event of breakthrough disease after an adequate trial period or if cost, availability, or tolerance is problematic, it is reasonable to switch from one maintenance treatment to another.

Maintenance for Myelin Oligodendrocyte Glycoprotein Immunoglobulin G Disease

It remains unclear when to initiate maintenance immunotherapy in patients with MOG-IgG–associated diseases. Up to 50% of patients with MOG-IgG–related disease may not relapse, especially those who revert to seronegative status. Factors to consider prior to initiating maintenance therapy include whether relapse has occurred following the initial attack, the severity of, and degree of recovery from relapses. There are no current guidelines or clinical trial data for the treatment of MOG-IgG disease. Preliminary experience with this recently recognized disease defined largely by the antibody suggests that maintenance immunotherapies for MOG-IgG disease should be similar to the agents used for AQP4-IgG–associated NMOSD.

OUTCOMES

Mortality in Neuromyelitis Optica Spectrum Disorder

Mortality rates in NMOSD have improved in recent years. Pre–AQP4-IgG studies reported 5-year survival rate of 68% and median survival of 17.5 years. More recent studies report mortality rates under 25% in those with disease duration of less than 10 years. Most NMOSD-related deaths result from respiratory failure in the context of cervical myelitis, brainstem inflammation, and diencephalic dysfunction accompanied by manifestations such as syndrome of inappropriate secretion of antidiuretic hormone and hypothermia. The improvement in mortality rate is probably the result of early diagnosis and prompt institution of effective treatment.

In a study of 427 NMOSD patients of whom 30 were deceased, the average age at death was 52 years and at a mean disease duration of 7 years. African Americans and Afro-Caribbean Hispanics had higher mortality rates than whites. Early attack frequency, poor recovery from first attack, and older age of onset may increase the risk of death in NMOSD.

Disability in Neuromyelitis Optica Spectrum Disorder

AQP4-IgG–associated NMOSD is associated with poor recovery from relapses with severe disability, but this is variable, and "benign" cases have been described. Disability in NMOSD mainly affects visual, motor, and ambulatory functions. Cognitive impairment has also been described in 30% to 50% of patients, although less commonly than in MS.

About 20% to 40% of NMOSD patients experience severe permanent motor and visual disability after the initial event. Recent studies find that 40% of patients are unable to walk without assistance and 20% have visual acuity of 20/200 or worse in at least one eye after first attack. The disability accumulation is stepwise. The average time to require gait assistance with a cane, crutches, or walker is 6 to 8 years and to become wheelchair confided is 22 years.

Age, gender, and ethnicity have been inconsistently associated with outcome. However, younger age at onset and male sex are more likely to predict visual disability, whereas older age onset is more predictive of motor disability. Afro-Caribbeans may have higher relapse rates than whites. An AQP4-IgG status is not convincingly associated with specific outcomes among patients with NMOSD with or without positive AQP4-IgG. High disability at onset predicts poor outcomes, and long-term immunotherapy reduces disability from attacks.

Around 50% of patients with MOG-IgG disease are permanently disabled after 2 years from onset. These disabilities include visual dysfunction in 16%, mobility limitation in 7%, bladder and bowel dysfunction (20%-30%), and erectile dysfunction (20% of men). About 35% relapsed after median disease duration of 16 months. Patients who present with ON are more likely to recover than those presenting with TM.

74 Autoimmune Encephalitis and Meningitis

Andrew McKeon, Divyanshu Dubey, Eoin P. Flanagan, Anastasia Zekeridou, and Sean J. Pittock

KEY POINTS

1. Autoimmune encephalitis and meningitis are recognized as common entities in neurologic practice. Incidence is equivalent to infectious causes.
2. Autoimmune encephalitis clinical phenotypes include classical disorders, such as limbic and brainstem encephalitis, and restricted phenotypes, such as autoimmune epilepsy.
3. *N*-methyl-D-aspartate receptor encephalitis classically has a neuropsychiatric prodrome.
4. Some recognizable clinico-radiologic-serologic entities include autoimmune glial fibrillary acidic protein astrocytopathy (a form of meningoencephalitis) and γ-aminobutyric acid A receptor encephalitis.
5. Magnetic resonance imaging of brain is often normal in autoimmune encephalitis. Positron emission tomography imaging and serum and cerebrospinal fluid neural antibody testing aid clinical diagnosis. Testing both serum and cerebrospinal fluid improves overall sensitivity.
6. Neural antibody testing is often negative in autoimmune encephalitis. Other clinical clues include rapid-onset, fluctuating disease course and personal history of autoimmunity.
7. Certain immunoglobulin Gs have association with specific cancer types (paraneoplastic), which should prompt a cancer search.
8. Early immunotherapy is critical in definite autoimmune encephalitis cases.

INTRODUCTION

Neurologic disorders attributable to infection or inflammation of brain parenchyma (encephalitis) or the meninges (meningitis) are common referrals in both hospital and ambulatory neurologic practices. For many patients, a straightforward diagnosis, such as herpes simplex encephalitis, or autoimmune limbic encephalitis is rapidly discerned. For other patients, diagnostic uncertainty persists. Historically, and to a lesser extent currently, many patients are repeatedly investigated for an infectious cause, without consideration of noninfectious causes, or are treated empirically for an inflammatory or autoimmune cause after limited testing for one or two rare disorders.

Over the course of the last two decades, autoimmune causes for encephalitis and meningitis (predominantly encephalitis) have been increasingly recognized. Much of this recognition has been spurred by the discovery of a multitude of autoantibody (immunoglobulin G [IgG] isotype) biomarkers of central nervous system (CNS) autoimmune diseases. In addition, diagnostic criteria and detailed descriptions of the phenotypic spectrum have emerged.

In addition to limbic encephalitis, where patients have a triad of cognitive, psychiatric, and epileptic symptoms, other phenotypic manifestations of CNS autoimmunity are now recognized. Examples include psychiatric prodrome (encountered in *N*-methyl-D-aspartate receptor [NMDAR] encephalitis) and meningeal symptoms and signs (characteristic of autoimmune glial fibrillary acidic protein [GFAP] astrocytopathy). Improved disease recognition has led to increased incidence, with autoimmune causes of encephalitis now on an epidemiologic par with infectious causes.

Discovery of neural-specific IgG autoantibodies has provided some clues to understanding disease pathophysiology. Because some autoimmune CNS disorders have a paraneoplastic cause (neurologic disease occurring in the context of a neural protein-expressing neoplasm), a search for occult systemic cancer may be undertaken. Treatment of any underlying neoplasm may contribute to neurologic improvements. Recognition of encephalitis as having an autoimmune cause prompts initiation of immune therapies (such as corticosteroids, plasma exchange, or immune suppressants). Early treatment is known to improve neurologic prognosis in many patients. Serologic diagnosis can also be informative for treatment choices and prognosis.

Although these novel neural IgG biomarkers have improved diagnostic sensitivity for autoimmune CNS disorders, improved clinical recognition has also been informative for the existence of seronegative cases (as high as 50% of cases in some series). Careful evaluation of the history, examination, and nonneural IgG antibody testing (eg, thyroid autoantibodies) may assist in reaching an autoimmune diagnosis in the absence of neural IgG positivity. In those patients, an objectively defined sustained response to immune therapy may confirm the diagnosis.

EPIDEMIOLOGY

Evaluation of 761 cases of encephalitis of uncertain etiology in individuals aged 30 years, or younger, referred to the California Encephalitis Project between September 2007 and February 2011 demonstrated the frequency of NMDAR encephalitis matched

viral etiologies. A recent population-based epidemiology study of autoimmune encephalitis in Olmsted County, Minnesota, demonstrated that autoimmune encephalitis had a prevalence of 13.7 per 100,000 people. The age- and sex-adjusted prevalence of autoimmune encephalitis was found to be comparable to infectious encephalitis (11.6 per 100,000). Furthermore, the incidence of autoimmune encephalitis is increasing over time from 0.4 per 100,000 person-years in 1995-2005 to 1.2 per 100,000 person-years in 2006-2015, mostly attributable to increased detection of autoantibody-positive cases. The most frequently identified neural autoantibodies associated with autoimmune encephalitis were myelin oligodendrocyte glycoprotein (MOG) and glutamic acid decarboxylase 65 kDa isoform, detected in cerebrospinal fluid (CSF) or in serum at high titer [>20.0 nmol/L]). Of note, the incidence and prevalence of autoimmune encephalitis was found to be higher among African Americans than Caucasians.

PATHOBIOLOGY

Immunobiology

Antigenic proteins undergoing immune surveillance are processed by antigen-presenting cells (dendritic cells in the early stages, B lymphocytes later in the immune response) and presented to antigen-specific cluster of differentiation (CD) 4^+ T helper lymphocytes. These in turn have the potential to trigger generation of cell lineages producing immunologic effectors. Some differentiate into $CD8^+$ cytotoxic T cells. Some B-cell populations mature into antibody-producing plasma cells. The subcellular location of the antigen targeted during the autoimmune response, intracellular or plasma membrane bound, may give some clues to the pathophysiology of autoimmune encephalitis (Fig. 74.1), at the effector stage, either cytotoxic T lymphocyte or IgG autoantibody mediated, respectively.

FIGURE 74.1 Mechanisms of neurologic autoimmunity. Neural antigens released (intracellular in *green*, cell membrane in *blue*) from lysed tumor cells, after initial attack by innate effectors, or from damaged neurons after viral attack, are phagocytosed and processed by antigen-presenting cells (APCs). The APCs migrate to regional lymph nodes and prime naive cluster of differentiation (CD) 4^+ T lymphocytes via the major histocompatibility complex (MHC) 2 pathway. Activated T cells proliferate and differentiate into helper (and regulatory) cells. The $CD4^+$ helper cells activate B cells that have engaged the same antigen on their receptors and differentiate into plasma cells secreting high-affinity antibodies. Cross-presentation of antigenic peptides via the MHC1 pathway from the APCs prime antigen-specific $CD8^+$ cytotoxic effector T lymphocytes (CTLs). Circulating CTLs attack cells expressing MHC1-complexed antigenic peptides, which arise from degradation of intracellular neural antigens by the proteasome, and are subsequently loaded on MHC1 molecules in the endoplasmic reticulum. Immunoglobulin Gs that bind to the extracellular domain of neural plasma membrane proteins may lead to antigen internalization, functional blockade, antibody-dependent cellular cytotoxicity (ADCC) or complement activation and cell lysis.

The trigger of autoimmunity in cases of autoimmune encephalitis is often unknown. Some are associated with malignancies or prior viral CNS infections. Paraneoplastic neurologic disorders occur in the context of robust antitumor immune responses against neural antigens expressed in cancers that are also physiologically expressed in the nervous system (known as *onconeural antigens*; see Fig. 74.1). Onconeural antigens can be expressed by tumors in both native and mutated forms (neo-epitopes). In the tumor bed, antigen is released after tumor cell death, processed, and presented by antigen-presenting cells to the T cells in regional lymph nodes. The $CD4^+$ helper T cells primed via the major histocompatibility complex (MHC) 2 pathway, activate antigen-specific B cells to differentiate into plasma cells and produce antibodies. Cross-presentation of an antigen via the MHC class I pathway primes $CD8^+$ cytotoxic T cells that then migrate to both cancer site and CNS and can exert their cytotoxic effect. In the last decade, immune checkpoint inhibitors for cancer treatment have become available. These monoclonal autoantibodies target coinhibitory, negative regulatory steps of the immune response and thus enhance antitumor immunity but also autoimmunity. Neurologic manifestations have been reported.

Neuronal and glial synaptic membrane proteins can be targeted by IgGs that are potentially pathogenic and responsible for the disease manifestations. These IgGs bind to extracellular epitopes of ionotropic and metabotropic receptors, water channels, and neural adhesion proteins. The effects of these autoantibodies have been recapitulated in live neuronal and astrocytic cultures in vitro. A major mechanism of action of multiple synaptic IgGs implicated in autoimmune encephalitis is antigen binding, cross-linking, and subsequent internalization and antigen degradation. This mechanism has been studied in detail in patients with IgGs specific for NMDAR or aquaporin-4 (AQP4) CNS water channel, and this effect of the antibodies is reversible upon antibody removal in vitro. Antibody-dependent cell-mediated cytotoxicity and complement cascade activation have also been implicated in AQP4 autoimmunity. Disruption of protein-protein interactions by autoantibodies, and thus interference with the protein target's function, is likely the major mechanism of action in diseases that are primarily mediated by IgG4 autoantibodies, such as leucine-rich glioma–inactivated protein 1 (LGI1) and contactin-associated protein 2 encephalitides. Animal models of passive transfer of synaptic autoantibodies delivered directly to the CNS compartment (in NMDAR encephalitis) or to the periphery (contactin-associated protein 2 encephalitis) have reproduced clinical and histopathologic findings of these diseases.

In contrast to IgGs targeting neural synapses, IgGs specific for intracellular neural antigens do not exert cell-specific cytotoxicity themselves, but nonetheless are biomarkers of likely effector T cell–mediated disease. Cytotoxic T cells can only recognize antigen if presented as a MHC1-complexed antigen-derived peptide (see Fig. 74.1).

In recent years, postinfectious autoimmune encephalitides have been recognized, mainly after herpes simplex virus encephalitis. It is hypothesized that local release of neural antigens from neuronal death leads to immune system activation and antigen-specific autoimmunity rather than molecular mimicry. This has also been reproduced in an animal model. Genetic susceptibility to autoimmunity has also been implicated. Human leukocyte antigen associations have been found for some patients with antibody-associated neurologic autoimmunity, such as LGI1 encephalitis. At the time pf writing, the coronavirus 2019/2020 (COVID19) outbreak has presented opportunities to explore the pathophysiology of postinfectious inflammatory encephalitis further.

Immunopathology

Tumors from patients with paraneoplastic neurologic autoimmunity often contain inflammatory onconeural antigen-directed plasma cells and T cells within the tumors. Brain pathology often reflects the pathophysiologic mechanisms described earlier (Fig. 74.2). In patients with T cell–mediated autoimmunity, such as that targeting amphiphysin or Hu, there is extensive immune infiltration consisting mostly of cytotoxic T cells and macrophages and neuronal loss. In contrast, in autopsy samples from patients with NMDAR encephalitis, there are moderate inflammatory infiltrates, consisting of plasma cells, IgG deposition, and microglial activation. In AQP4 autoimmunity, complement plays an important role in the disease pathogenesis. In AQP4 autoimmunity lesions, there are products of complement activation around blood vessels and immunoglobulin deposits. In contrast, in MOG autoimmunity, demyelination is the primary pathologic feature.

DIAGNOSIS

Clinical Manifestations

Autoimmune Meningitis

Autoimmune meningitis can present with one or more of headache, blurred vision, hearing loss, tinnitus, fever, vomiting, and, sometimes, cranial nerve signs. The only disorder in which a neural IgG has been described in a meningitic context is autoimmune GFAP astrocytopathy. Those patients generally have encephalitic signs also. However, autoimmune pachymeningitis and leptomeningitis can occur in patients with or without systemic and other organ-specific autoimmune disorders, such as systemic lupus erythematous, rheumatoid arthritis, and Crohn disease. Pachymeningitis may occasionally arise in patients with a fibroinflammatory disorder known as *IgG4-related disease*, so called because of the dense infiltration of IgG4-positive plasma cells in a variety of organs (pancreas, salivary glands, thyroid, mediastinum, retroperitoneum, kidney, retro-orbital space). Other patients may have a chronic inflammatory meningitis complicating CNS inflammatory disorders such as sarcoidosis or Behçet disease or occurring in isolation without further case definition. A form of recurrent idiopathic meningitis, known as *Mollaret meningitis*, may have an autoimmune or other inflammatory cause.

Autoimmune Encephalitis: General Features

Autoimmune encephalopathy typically presents with subacute onset of cognitive decline, delirium, and psychiatric symptoms (mood change or psychosis). Accompanying symptoms include headache, blurred vision, and disrupted sleep. In addition, patients may have one or more of accompanying movement disorders (ataxia, myoclonus or chorea) (▶ Videos 74.1 and 2). There may be additional clues to an autoimmune diagnosis (Table 74.1). For patients with a paraneoplastic cause, encephalopathy may be a component of a multifocal neurologic disorder. Comorbid neurologic disorders may include myelopathic symptoms and signs, peripheral neuropathy, or neuromuscular junction disorder (myasthenia gravis or Lambert-Eaton syndrome).

There are certain clinical syndromes that are clinically classical, and most have diverse neural antibody associations (eg, limbic encephalitis). Other clinical syndromes, or clinico-radiologic entities, are synonymous with particular IgG findings (eg, NMDAR

FIGURE 74.2 Examples of brain and tumor immunopathology from patients with neurologic autoimmunity. **A:** Perivascular and parenchymal mononuclear leukocyte infiltrates in the brain of a patient with amphiphysin-immunoglobulin G (IgG) autoimmunity **(i)**; in the parenchyma are mostly cluster of differentiation (CD) 8^+ **(ii)** or macrophages **(iii)**, whereas B-cells are located in the perivascular locations **(iv)**. (From Pittock SJ, Lucchinetti CF, Parisi JE, et al. Autoimmune GFAP astrocytopathy: prospective evaluation of 90 patients in1 year. *J Neuroimmunol*. 2018;321:157-163, Fig. 3A-D.) **D:** Immunohistochemical staining of a Merkel cell metastatic carcinoma from a patient with neuronal intermediate filament autoimmunity (NIF) reveals expression of α internexin **(i)**, NIF light chain **(ii)**, NIF medium chain **(iii)**, and NIF heavy chain **(iv)**, which matched the patients IgG serologic profile. (From Basal E, Zalewski N, Kryzer TJ, et al, Paraneoplastic neuronal intermediate filament autoimmunity. *Neurology*. 2018;91[18]:e1677-e1689, Fig. 6.)

TABLE 74.1 Clues to an Autoimmune Encephalitis Diagnosis

Subacute onset with rapid progression of cognitive, behavioral, psychiatric symptoms, seizures
Fluctuating clinical course, with partial or full spontaneous remissions
Tremulousness, myoclonus
Headache, meningism, blurred vision
Personal or family history of autoimmune disease
History of cancer
Nonneural antibodies positive (eg, thyroid autoantibodies)
CNS inflammation on MRI or global hypometabolism on PET imaging
CNS inflammation in CSF (elevated white cell count, IgG index or synthesis rate, oligoclonal bands)
Dramatic objective response to immune therapies

Abbreviations: CNS, central nervous system; CSF, cerebrospinal fluid; IgG, immunoglobulin G; MRI, magnetic resonance imaging; PET, positron emission tomography.

encephalitis). Many patients present with restricted forms of these (eg, autoimmune epilepsy in LGI1 encephalitis) or have unique or rare presentations. Diagnostic criteria for autoimmune encephalopathy have been proposed by Graus et al (2016).

Classical Encephalitis Syndromes

Limbic Encephalitis

Limbic encephalitis is a classic CNS autoimmune disorder. Patients typically present with delirium, mood change, memory and personality disturbance, and focal seizures of mesial temporal type with or without secondary generalization. Head magnetic resonance imaging (MRI) usually reveals unilateral or bilateral T2 sequence signal abnormalities in mesial temporal regions, with or without enhancement visible on T1 sequence postgadolinium. Electroencephalography (EEG) may reveal unilateral or bilateral temporal slowing or epileptiform discharges. Neural autoantibody findings are diverse. Some are highly predictive of cancer (eg, anti-Hu), whereas other are predictive of a response to immunotherapy (eg, LGI1 antibody) (▶ Video 74.3).

Brainstem Encephalitis

Presenting symptoms include one or more of cranial neuropathies, eye movement disorders, vertigo, nausea and vomiting (sometimes intractable), postural instability, and parkinsonism. Jaw closing dystonia is particularly associated with brainstem encephalitis accompanying antineuronal nuclear antibody (ANNA) 2 (anti-Ri) (▶ Video 74.4). Brainstem encephalitis is a common presentation for patients with either Ma2 antibody (also known as *anti-Ta*, usually young men with testicular carcinoma) or both Ma1 and Ma2 antibodies (also known as *anti-Ma*, men and women with heterogenous cancer types). Sensorineural hearing loss and tinnitus frequently accompanies Kelch-like protein 11 autoimmune brainstem encephalitis. The MRI of brain may be normal or demonstrate T2 abnormalities in the brainstem and/or cerebellum.

Opsoclonus-Myoclonus Syndrome

Opsoclonus-myoclonus syndrome (also known as "dancing-eyes, dancing-feet syndrome") is pathognomonic for an autoimmune diagnosis, either parainfectious, paraneoplastic, or idiopathic autoimmune (see Video 74.1). Patients present with vertigo, dizziness, nausea and vomiting, tremulousness, and imbalance. Neurologic exam reveals generalized myoclonic jerks and lightning-like haphazard eye movements, consistent with myoclonus of the extraocular muscles (opsoclonus). Commonly encountered neoplasms include neuroblastoma and lung carcinoma and breast carcinoma (in adults). Rather than opsoclonus-myoclonus syndrome, some patients may present with opsoclonus or limb and truncal myoclonus in isolation, with or without encephalopathy.

Morvan Syndrome

Morvan syndrome is a rare multifocal disorder, usually accompanying contactin-associated protein 2 autoimmunity. Features include encephalitis, sleep disturbance, dysautonomia, and peripheral nerve hyperexcitability. Thymoma is the typical oncologic accompaniment.

Progressive Encephalomyelitis With Rigidity and Myoclonus

Progressive encephalomyelitis with rigidity and myoclonus (PERM) is within the spectrum of CNS hyperexcitability disorders, also known as *stiff-person spectrum disorders*. Exaggerated startle response, hypertonia and superimposed spasms are common to both stiff-person syndrome (▶ Video 74.5) and PERM. However, PERM is more widespread and severe and generally includes encephalopathic features. The glutamic acid decarboxylase 65 kDa isoform antibody is detected in some of these patients, although historically, most PERM patients had been seronegative. Glycine receptor and dipeptidyl-peptidase-like protein 6 antibodies are now recognized as diagnostic markers of PERM.

Clinically Restricted Forms

Autoimmune Epilepsy

Some patients with autoimmune encephalitis present with seizures only or a predominance of seizures. These more restricted clinical presentations merit special mention, as they may be overlooked as having an autoimmune cause because of the nonclassical presentations. Autoimmune epilepsy may be defined as seizures as the exclusive or major presenting symptom, where an autoimmune cause was suspected on the basis of detection of neural antibody, inflammatory CSF, or head MRI, consistent with the diagnosis. Patients with autoimmune epilepsy are typically lacking classical epilepsy risk factors, such as a history of acquired brain injury and family history of epilepsy. Most affected patients have several of these factors, and one factor in isolation is poorly predictive of an autoimmune cause. Two additional syndromes are suspected to have an autoimmune cause because of the rapidity of onset and severe clinical course, although most patients have an idiopathic illness without immunologic biomarkers detected. These are known as *new-onset refractory status epilepticus* in adults and *fever-induced refractory epileptic encephalopathy syndrome* in children. Dramatic clinical responses attributed to an interleukin 1 receptor antagonist (anakinra) in some reported cases is supportive of an immunologic etiology.

Autoimmune Dementia

Other patients do not have seizures or altered sensorium but present with rapidly progressive cognitive loss. Autoimmune dementia phenotypes may resemble Creutzfeldt-Jakob disease or rapidly progressive Alzheimer disease or Lewy body disease. Tremulousness and headache at presentation, marked fluctuations in the clinical course, and spontaneous remission suggest an autoimmune cause.

Nonlimbic Encephalitis: Serologically Defined Entities

NMDA Receptor Antibody Encephalitis

Patients with NMDAR antibody (targeting the GluN1 [NR1] subunit) have a fairly stereotyped neurologic disorder, as described below by Dalmau and colleagues. Prodromal symptoms include headache, fever, nausea, vomiting, diarrhea, or upper respiratory tract symptoms. Patients develop psychiatric symptoms (anxiety, insomnia, fear, delusions, mania, and paranoia), and many initially come to the attention of psychiatrists. Other behavioral changes include social withdrawal and stereotyped behavior. Amnesia and an unusual language disorder (noncortical aphasia) are common. The behavioral changes in children may be less specific and include temper tantrums and hyperactivity. Neurologic disorders including seizures and dyskinesias are frequent. After these initial symptoms, in both adults and children, decreased responsiveness often ensues. Movement disorders include oro-lingual-facial dyskinesias, generalized chorea, oculogyric crisis, dystonia, and rigidity. Frequent autonomic manifestations include hyperthermia, tachycardia, hypersalivation, hypertension, bradycardia, hypotension, urinary incontinence, and erectile dysfunction. Hypoventilation, necessitating prolonged ventilatory support (often months) may be required. Dissociative responses similar to those caused by NMDAR antagonists (eg, phencyclidine or ketamine) have been observed (eg, resisting eye opening despite lack of response to painful stimuli).

Autoimmune GFAP Astrocytopathy

Affected patients present with symptoms of meningitis (headache and neck ache), encephalitis (delirium, tremor, seizures, or psychiatric symptoms), and myelitis (sensory symptoms and weakness). Optic papillitis (disc swelling causing blurred vision) is common. The CNS inflammation is evident on T1 postgadolinium (enhancement of GFAP-enriched CNS regions; Fig. 74.3F) and in lymphocyte-predominant CSF white cell count elevation. The CSF is more sensitive and specific than serum for GFAP-IgG testing. Ovarian teratoma commonly coexists, particularly among patients with accompanying NMDAR or AQP4 autoimmunity. Corticosteroid responsiveness is a hallmark of the disease. Relapses occur in approximately 20% of patients, necessitating transition to a steroid-sparing drug during prednisone taper.

$GABA_A$ Receptor Encephalitis

Affected patients (adults or children) typically present with multifocal antiepileptic drug-refractory seizures, other encephalitic symptoms, and abnormalities on brain MRI (multifocal, non–diffusion-restricting, nonenhancing, medium- to large-sized cortical, juxtacortical, and subcortical lesions) (Fig. 74.3B).

Encephalitis Accompanying Neuromyelitis Optica Spectrum Disorders, Optic Neuritis, or Myelitis

Optic neuritis and transverse myelitis (radiologically longitudinally extensive), either single episode or recurrent, are characteristic of both AQP4 autoimmunity and MOG autoimmunity. Encephalitis can occur with either disorder also. Acute disseminated encephalomyelitis is a characteristic syndrome accompanying MOG autoimmunity. Patients, most commonly children, present with fever, encephalopathy, and multifocal neurologic dysfunction. The MRI demonstrates large inflammatory-appearing lesions of the brain (Fig. 74.3E) and, often also, the spinal cord. Although optic neuritis and myelitis predominate in AQP4 autoimmunity, patients may present with brain symptoms or develop asymptomatic brain lesions radiologically during the clinical course.

Neural IgG Seronegative Autoimmune Encephalopathy

In some instances, the more generic term of autoimmune encephalopathy, or encephalitis, without reference to a specific neural antibody is appropriate. This is because the neural antibody detected has less specificity for encephalitis (eg, P/Q type calcium channel antibody), or no neural antibody has been detected, but other clues for an autoimmune diagnosis are discovered (see Table 74.1). These clues could include one or more of a history of coexisting autoimmune diseases (eg, thyroid disease or pernicious anemia), the detection of nonneural autoantibodies (such as thyroid peroxidase or connective tissue disease autoantibodies) in serum, an inflammatory spinal fluid, an encephalitic-appearing head MRI, and a response to immunotherapy. Both Hashimoto encephalopathy and steroid-responsive encephalopathy associated with autoimmune thyroiditis refer to a triad of encephalopathy (commonly with stroke-like episodes, negative MRI), thyroid autoimmunity, and clinical improvements with immunotherapy. Because both thyroid autoantibodies and cognitive symptoms are generally common, including among healthy individuals, this example serves to underline the importance of objectifying reported cognitive improvements with immunotherapy.

Imaging

MRI Brain Imaging

Head MRI with gadolinium is an essential diagnostic test in the evaluation of autoimmune encephalitis and meningitis. The presence of unilateral (Fig. 74.3A1) or bilateral (Fig. 74.3C) mesial temporal lobe T2 hyperintensities is supportive of autoimmune limbic encephalitis and may be accompanied by gadolinium enhancement. Occasionally, seizure-related signal abnormalities in those with status epilepticus can result in mesial temporal T2 hyperintensities mimicking limbic encephalitis. Focally restricted diffusion, thalamic hyperintensities, and gyral enhancement are also recognized as seizure-related MRI findings. In NMDAR encephalitis, most patients have normal brain MRI. In those with abnormalities, a wide variety of T2-signal abnormalities have been reported, and there may be an overlap with other disorders which routinely produce MRI abnormalities (such as MOG and GFAP autoimmunity).

The MOG autoantibodies, in addition to optic neuritis and myelitis, are associated with acute disseminated encephalomyelitis-like multifocal T2 hyperintensities in the white matter and deep gray matter (thalamus and basal ganglia; see Fig. 74.3E). In addition to typical radiologic findings of optic neuritis and myelitis, patients with AQP4-IgG seropositive neuromyelitis optica spectrum disorders develop brain lesions in two-thirds of cases, with or without clinical accompaniments, such as encephalopathy. Peri-third and fourth ventricular lesions (including the area postrema) are typical.

The γ-aminobutyric acid (GABA) A receptor antibody encephalitis T2-signal abnormalities are multifocal involving the white and gray matter (see Fig. 74.3B). Diencephalic lesions adjacent to the third ventricle are reported with Ma2 encephalitis with an accompanying narcolepsy/cataplexy phenotype (Fig. 74.3A2). Basal ganglia T2 hyperintensities with accompanying hyperkinetic movement disorders have been reported with phosphodiesterase

FIGURE 74.3 Imaging abnormalities in autoimmune encephalitis. In a patient with Ma2 encephalitis, axial magnetic resonance imaging (MRI) reveals T2 hyperintensity in the left mesial temporal lobe (**A1**, *arrow*) which is accompanied by bilateral midline T2 hyperintensity in the hypothalamus (**A2**, *arrow*). **B:** In a patient with γ-aminobutyric acid A receptor encephalitis, axial MRI shows a corticosubcortical T2 hyperintensity in the right temporal lobe *(arrow)*. **C:** In a patient with α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic (AMPA) receptor antibody encephalitis, coronal MRI reveals bilateral T2 hyperintensities in the mesial temporal lobe *(arrows)*. **D:** In a patient with leucine-rich glioma–inactivated protein 1 antibody encephalitis, coronal MRI reveals right caudate and putamen T2 hyperintensity *(arrow)*. **E:** In a patient with acute disseminated encephalomyelitis (myelin oligodendrocyte glycoprotein-immunoglobulin G positive), axial MRI reveals bilateral thalamic T2 hyperintensities *(arrows)*. **F:** Axial postgadolinium MRI reveals radial perivascular enhancement *(arrows)* in autoimmune glial fibrillary acidic protein astrocytopathy. **G:** In a patient with AMPA receptor antibody encephalitis, whole-body ^{18}F-fluorodeoxyglucose positron emission tomography (FDG-PET) reveals a hypermetabolic lung mass *(arrow)*, confirmed to be small cell carcinoma at histology. **H:** Axial brain FDG-PET reveals right mesial temporal hypermetabolism *(arrow)*.

10A and collapsin-response mediator protein (CRMP) 5 antibodies. Basal ganglia T1 or T2 hyperintensities occasionally accompany faciobrachial dystonic seizures in LGI1 encephalitis (Fig. 74.3D).

The presence of linear radial perivascular enhancement extending outward from the ventricles is suggestive of autoimmune GFAP astrocytopathy and isolated leptomeningeal enhancement is also frequently encountered (see Fig. 74.3F).

Several other disorders, with possible autoimmune cause, but no antibody biomarker known, also have classical radiologic findings. The presence of infarcts, microhemorrhages, and leptomeningeal enhancement is suggestive of primary CNS vasculitis or amyloid-β related angiitis. Circular "snowball-like" T2 hyperintensities of the corpus collosum suggest Susac syndrome, a disorder characterized by a triad of encephalopathy, branch retinal artery occlusions, and hearing loss. Behçet disease is frequently associated with brainstem lesions but also may result in cerebral venous sinus thrombosis or be associated with leptomeningeal (pia and arachnoid) enhancement in association with a chronic meningitis. Other inflammatory etiologies of meningitis associated with leptomeningeal enhancement include neurosarcoid (which has a predilection for the basilar meninges) and rheumatoid arthritis-associated meningitis. Autoimmune disorders most often associated with pachymeningeal (dural) enhancement include IgG4-related disease and granulomatosis with polyangiitis (previously termed *Wegener granulomatosis*).

Positron Emission Tomography

^{18}F-Flourodeoxyglucose positron emission tomography (PET) is one of the most sensitive tests for early changes in autoimmune encephalitis, although lacking specificity. Glucose hypometabolism is the most common finding in autoimmune encephalitis, but hypermetabolism may occasionally coexist or rarely occur in isolation (Fig. 74.3H). Mesial occipital glucose hypometabolism has been reported to be the most common finding in NMDAR encephalitis. Basal ganglia hyper- or hypometabolism may accompany faciobrachial dystonic seizures in LGI1 antibody encephalitis.

Electroencephalography

The EEG plays a vital role in diagnosis and management of autoimmune encephalitis. Although not specific for autoimmune encephalitis, demonstration of encephalopathy electrographically (diffuse delta or theta slowing) assists in objectifying cerebral dysfunction and serves as a baseline for future comparison during treatment and patient follow-up. The NMDAR and LGI1 encephalitides are sometimes accompanied by specific EEG findings or semiologies.

Extreme delta brush was described as a characteristic finding in NMDAR encephalitis patients on continuous EEG monitoring in the neurointensive care unit (Fig. 74.4). Extreme delta brush consists of rhythmic delta activity at 1 to 3 Hz with superimposed

FIGURE 74.4 Extreme delta brush in a patient with *N*-methyl-D-aspartate receptor encephalitis. Fast beta rhythm "riding on" diffuse slow waves. (Courtesy Dr. Jeffrey Britton, Mayo Clinic.)

burst of rhythmic beta activity at 20 to 30 Hz riding on each delta wave. It is usually present in severely affected patients, in both adult and pediatric age groups. Faciobrachial dystonic seizures are pathognomonic for LGI1 encephalitis (see Video 74.3). Ictal EEG during faciobrachial dystonic seizures is usually obscured by prominent muscle artifact. However, rhythmic slow wave activity over the contralateral frontal or frontotemporal region followed by diffuse EEG attenuation can occasionally be seen.

Antibody Testing

Evaluations of serum and CSF for neural-specific IgG biomarkers and less specific clues (such as thyroid antibodies or elevated CSF white cell count) should be undertaken in suspected autoimmune encephalitis cases.

Informative nonneural autoantibody specificities may be organ specific (such as thyroid autoantibodies) or non–organ specific (such as antinuclear, antismooth muscle, or antimitochondrial antibodies). These markers per se lack specificity for neurologic autoimmunity. The detection in CSF of elevated protein, white cell count, CSF-exclusive oligoclonal bands, IgG index, or IgG synthesis rate also supports an autoimmune etiology. However, these parameters lack specificity for an autoimmune cause and may be detected in other inflammatory CNS disorders for which there are no specific biomarkers (eg, multiple sclerosis).

Antigen targets of neural IgG autoantibodies fall into two broad classes based on subcellular location: intracellular and cell-surface (extracellular) (Tables 74.2 and 74.3). Screening tests for these autoantibodies include immunohistochemistry (tissue-based or cell-based; Fig. 74.5), enzyme-linked immunosorbent assay, and immunoprecipitation assays. In some instances, reflex testing may be indicated to confirm antigen-specificity (by Western blot or cell based) or to quantitate an end point value or titer. Some autoantibodies are more readily detected in serum (eg, LGI1-IgG) and others in CSF (NMDAR antibody); thus, the diagnostic yield is maximized by testing both serum and CSF, simultaneously or sequentially.

TABLE 74.2 Neural Immunoglobulin G Autoantibodies With Specificity for Intracellular Antigens (Nuclear, Cytoplasmic, or Nucleolar) in Autoimmune Encephalitis

Antibody	Antigen	Neurologic Presentations	Oncologic Association
AGNA	SOX-1	Limbic encephalitis, neuropathy, Lambert-Eaton syndrome	Small cell carcinoma
Amphiphysin	Amphiphysin	Limbic encephalitis, aphasia, other subacute-onset dementias, stiff-person phenomena, myelopathy, neuropathy	Small cell carcinoma, breast adenocarcinoma
ANNA-1	ELAVL (Hu)	Limbic encephalitis, brainstem encephalitis, sensory autonomic and other peripheral neuropathies	Small cell carcinoma
ANNA-2	Nova 1, Nova 2 (Ri)	Dementia, limbic encephalitis, brainstem encephalitis, jaw dystonia, myelopathy, opsoclonus-myoclonus syndrome, peripheral neuropathy	Small cell carcinoma, breast adenocarcinoma
ANNA-3	Unknown	Brainstem encephalitis, limbic encephalitis, myelopathy, peripheral neuropathy	Aerodigestive carcinomas
AP3B2	AP3B2	Gait disorders (cerebellar, dorsal column, sensory ganglionopathy) and dysautonomia	None known
CRMP-5	CRMP-5	Cognitive disorders, chorea, ataxia, myelopathy, radiculopathy, neuropathy, Lambert-Eaton syndrome	Small cell carcinoma, thymoma
GAD65 (high titer)	GAD65	Limbic encephalitis, brainstem encephalitis, stiff-man syndrome, stiff-man phenomena, ataxia, seizures, ophthalmoplegia, parkinsonism, myelopathy	Thymoma; renal cell, breast or colon adenocarcinoma
GFAP	GFAP-α/GFAP-ε isoforms	Meningoencephalomyelitis	Teratoma, diverse other
GRAF/ARHGAP26	GRAF	Brainstem signs (eye movement abnormalities) and ataxia	GI hematologic
ITPR1	ITPR1	Brainstem signs (eye movement abnormalities) and ataxia	Breast, lung hematologic
Kelch-like protein 11	Kelch-like protein 11	Brainstem encephalitis, cerebellar ataxia, limbic encephalitis accompanied by hearing loss	Testicular germ cell tumors
Ma1, Ma2	PNMA1, PNMA2	Limbic encephalitis, brainstem encephalitis, ataxia	Testicular germ cell tumors (Ma2 only), diverse (Ma1, Ma2)
NIF	NF-L, NF-H, α-internexin	Encephalopathy, ataxia, myelopathy	Small cell carcinoma (NF-L–IgG)
PDE10A	PDE10A	Encephalopathy, movement disorders	Renal cell adenocarcinoma
PCA-1	CDR2, CDR2-like	Brainstem encephalitis, cerebellar ataxia, myelopathy, neuropathies	Müllerian/breast adenocarcinoma
PCA-2	MAP1B	Limbic encephalitis, ataxia, brainstem encephalitis, Lambert-Eaton syndrome, peripheral and autonomic neuropathies	Small cell carcinoma
Septin-5	Septin-5	Brainstem signs (eye movement abnormalities) and ataxia	None known

Abbreviations: AGNA, antiglial/neuronal nuclear antibody; ANNA, antineuronal nuclear antibody; CDR2, cerebellar degeneration protein-2; CRMP, collapsin-response mediator protein; ELAVL, ELAV-like protein; GAD65, glutamic acid decarboxylase, 65 kDa isoform; GFAP, glial fibrillary acidic protein; GI, gastrointestinal; IgG, immunoglobulin G; ITPR1, inositol triphosphate receptor-1; MAP1B, microtubule associated protein 1B; NF-H, neurofilament heavy chain; NF-L, neurofilament light chain; NIF, neuronal intermediate filament; PCA, Purkinje cell cytoplasmic antibody; PNMA, paraneoplastic Ma protein; SOX, SRY-Box; AP3B2, adaptor protein 3B2; GRAF, GTPas regulator associated with focal adhesion kinase 1; ARHGAP26, Rho GTPase activating protein 26; PDE10A, phosphodiesterase 10A.

TABLE 74.3 Neural Immunoglobulin G Autoantibodies With Specificity for Extracellular Domain of Receptors and Channels in Autoimmune Encephalitis

Antibody	Antigen	Oncologic Association	Neurologic Presentation
AMPA receptor	GluR1, GluR2	Thymic tumors, lung carcinomas, breast carcinoma	Limbic encephalitis, nystagmus, seizures
DPPX	DPPX (DPP6)	Rarely B-cell neoplasia	Encephalomyelitis
$GABA_A$ receptor	$GABA_A$ receptor	Thymoma	Multifocal lesional encephalitis
$GABA_B$ receptor	$GABA_B$ receptor	Small cell lung carcinoma, other neuroendocrine neoplasia	Limbic encephalitis, intractable seizures, orolingual dyskinesias
Glycine receptor	α_1 Subunit GlyR	Thymoma, lymphoma	Progressive encephalomyelitis with rigidity and myoclonus, stiff-person syndrome
IgLON-5	IgLON5	None known	Sleep disorders, encephalopathy, chorea, parkinsonism
LGI1/CAPSR2	LGI1, CASPR2	Thymoma	Limbic encephalitis, faciobrachial dystonic seizures and other seizure types, neuromuscular hyperexcitability
mGluR1	mGluR1	Hodgkin lymphoma, prostate adenocarcinoma	Ataxia, dysgeusia, vertigo, cognitive symptoms, seizures
mGluR5	mGluR5	Hodgkin lymphoma	Limbic encephalitis
MOG	MOG	None known	ADEM-like presentation in children, relapsing optic neuritis, transverse myelitis
Neuronal ganglionic AChR	Neuronal ganglionic AChR	Adenocarcinoma, thymoma, small cell carcinoma	Dysautonomia, peripheral somatic neuropathies, encephalopathies
NMDA receptor	GluN1	Ovarian teratoma	Anxiety, psychosis, seizures, encephalopathy, dyskinesia, hypoventilation, coma.
NMO	Aquaporin-4	Some reports of thymoma and other solid tumors	ADEM-like presentation in children, relapsing optic neuritis, transverse myelitis; circumventricular organ involvement (intractable nausea vomiting, hiccups, narcolepsy)
P/Q- and N-type calcium channel	P/Q and N-type calcium channels	Small cell carcinoma, breast or gynecologic adenocarcinoma	Encephalopathies, myelopathies, neuropathies, Lambert-Eaton syndrome

Abbreviations: AChR, acetylcholine receptor; ADEM, acute disseminated encephalomyelitis; AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic; CASPR2, contactin-associated protein 2; DPPX, dipeptidyl-peptidase-like protein 6; $GABA_A$, γ-aminobutyric acid type A; $GABA_B$, γ-aminobutyric acid type B; GluR1, glutamate receptor 1; GluR2, glutamate receptor 2; GlyR, glycine receptor; IgLON5, immunoglobulin-like protein family member 5; LGI1, leucine-rich glioma–inactivated protein 1; mGluR1, metabotropic glutamate receptor 1; mGluR5, metabotropic glutamate receptor 5; MOG, myelin oligodendrocyte glycoprotein; NMDA, *N*-methyl-D-aspartate; NMO, neuromyelitis optica; GluN1, glutamate receptor, NMDA type, subunit 1; GluR1, glutamate receptor 1; GluR2, glutamate receptor 2.

Antibodies detected in most classic paraneoplastic encephalitides recognize intracellular antigens (see Table 74.2). These antibodies usually have positive predictive values for very specific cancer types greater than 70% and thus help direct the search for cancer. Some more recently discovered examples have cancer significance less commonly (eg, GFAP-IgG). Antibodies directed at neural cell plasma membrane antigens (see Table 74.3) are more recently described and have varying positive predictive cancer values (eg, <10% for glycine receptor antibody vs 50% or greater for antibodies targeting NMDA, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic, and $GABA_B$ receptors). The response to one or more of steroids, intravenous immunoglobulin (IVIG), and plasma exchange is often excellent, with full neurologic remission possible.

Algorithmic testing for autoantibody profiles is a more sensitive diagnostic strategy than nominal physician-selected single antibody testing. For example, seropositivity for amphiphysin-IgG predicts either small cell carcinoma or breast adenocarcinoma, but the presence or absence of coexisting small cell carcinoma associated antibodies narrows that differential diagnosis.

The profile of antibodies detected may also guide immunotherapy and may also be informative for neurologic prognosis. Studies suggest that autoimmune neurologic disorders for which the antigens of marker IgGs are intracellular such as Hu (the target ANNA-1) rarely improve with antibody-depleting therapies. On the other hand, IgGs targeting neural cell surface receptors (such as the NMDAR IgG) do have a pathogenic role in effecting autoimmune CNS disorders, which may remit after antibody-depleting immunotherapy.

Cancer Workup

The cancer types encountered in paraneoplastic disorders, known antibody associations, and testing modalities that can assist in cancer detection and diagnosis are listed in Table 74.4. In the context of paraneoplastic disorders, the neurologic symptoms appear first in 70% of cases. Neoplasms are commonly limited to the primary site or may just be detectable at a regional lymph node or small, distant metastatic site. Thus, these neoplasms may be difficult to identify on conventional imaging. An informative neural autoantibody profile can assist in radiologic modality selection. For example, thymoma is identified in 85% of patients seropositive for all of muscle striational, acetylcholine receptor, and CRMP-5 autoantibodies. Lung carcinoma is identified in 80% of patients seropositive for all of P/Q-type and N-type calcium channel antibodies and SRY-Box (SOX) 1-IgG. In women, amphiphysin-IgG alone directs the physician toward

FIGURE 74.5 Characteristic immunoglobulin G (IgG) staining patterns of mouse tissue-based indirect immunofluorescence assay. **A:** Antineuronal nuclear antibody 1 (anti-Hu) produces staining of nuclei and myenteric plexus of adjacent gut *(arrow)* but not parietal cells **(top left). B,C:** Purkinje cell cytoplasmic antibody 2 **(B,** MAP1B-IgG) and neuronal intermediate filament IgG **(C)** can be differentiated by differences in synaptic and filamentous staining of cerebellum. **D,E:** α-Amino-3-hydroxy-5-methyl-4-isoxazolepropionic receptor antibody produces synaptic (neuropil) staining of the cerebellum **(D)** and hippocampus **(E). F:** Glial fibrillary acidic protein-IgG produces staining of the periventricular ependyma and astrocyte precursor-enriched subependymal layer but spares the choroid **(bottom left).**

either breast or lung cancer, but the coexistence of ANNA-1 (Hu) or CRMP-5-IgG predicts small cell lung cancer.

For suspected lung cancer or thymoma, high-resolution computed tomography (CT) of the chest is recommended in the first instance. The MRI of the chest is also a sensitive testing modality for thymoma. The PET is sensitive for evaluation of mediastinal lymph nodes for local metastatic disease. Tissue diagnosis should be pursued aggressively if a thoracic lesion or lymphadenopathy is identified. Fine-needle aspiration biopsy guided by transesophageal ultrasonography, transbronchial endoscopy, or CT yields tissue confirmation with varying success and complications. The CT of the abdomen and pelvis is helpful in identifying large primary visceral malignancies and metastases. Endoscopies are most sensitive and specific for identifying primary gastrointestinal malignancies.

For breast cancer evaluation, mammography is the gold standard. Tissue diagnosis of subtle abnormalities should be pursued. The MRI of the breast or sonography is helpful in some cases.

Evaluation of gynecologic cancer status may require sonography of the pelvis in addition to CT and manual pelvic examination. For Purkinje cell cytoplasmic antibody 1 (anti-Yo)-positive patients whose breast evaluation, pelvic imaging and examination, and serum cancer antigen 125 levels are all normal, exploratory laparotomy may reveal pelvic carcinoma (ovarian, fallopian tubal, or serous surface papillary adenocarcinoma). The most useful screening tests for ovarian teratoma (eg, in females with NMDAR encephalitis) include MRI and pelvic ultrasound with transvaginal views (if age appropriate). Serologic tumor markers (cancer antigen 125, β-human chorionic gonadotropin, α-fetoprotein, or testosterone) are not recommended in the diagnostic workup of such patients. In general, testicular ultrasonography is warranted in men with subacute brainstem/cerebellar/limbic encephalitis, whether or not Ma2 or Kelch-like protein 11 antibodies are detected.

If radiologic investigation fails to indicate an abnormality suspicious for cancer, whole-body fluorodeoxyglucose PET can be helpful in identifying cancers such as pulmonary and extrapulmonary small cell carcinoma, thyroid malignancies, and lymphoma) (Fig. 74.3G). The PET-CT is inadequate for evaluation of possible thymoma, teratoma, GI malignancy, and primary testicular tumors.

If the patient's autoantibody profile is highly predictive of cancer, and no cancer is detected at initial evaluation, repeat screening is recommended at 6- to 12-month intervals for up to 5 years. Patient-specific factors should also be considered. For children and women of childbearing age, MRI is preferred over CT to minimize radiation exposure. The total radiation exposure of PET body is equivalent to CT chest, abdomen, and pelvis with and without contrast, approximately 25 mSv, comparable to 8 years of natural background radiation.

MANAGEMENT

A rational therapeutic approach to autoimmune encephalitis and meningitis can be devised based on treatments that have been successfully applied in the past to a variety of other autoimmune disorders. For paraneoplastic encephalitis or meningitis, where

TABLE 74.4 Diagnostic Evaluation for Cancer in Suspected Paraneoplastic Neurologic Disorders[a]

Cancer Type	Neural Ab Specificities Associated	Diagnostic Imaging Tests	Blood Tests/Tumor Biomarkers	Comments
Breast adenocarcinoma	**High risk:** ANNA-2 (Ri), Ma1 and Ma2, amphiphysin, PCA-1 (Yo) **Low risk:** recoverin (anti-CAR), P/Q- and N-type VGCC, AQP4, GFAP, ITPR1, ARHGAP26 (GRAF1), AMPA receptor	Mammogram Breast MRI	CA 15-3 CA 27-29	Familial breast cancer—BRCA1 and BRCA2 Measurement of ER, PR, and HER2 should be performed on tissue.
Lung: pulmonary and extrapulmonary small cell cancer Also some non–small cell	**High risk:** ANNA-1 (Hu), ANNA-2 (Ri), ANNA-3, Zic4, SOX1, amphiphysin, CRMP-5, PCA-2 (MAP1B), recoverin **Low risk:** Ma1 and Ma2, Ma2 alone, $GABA_B$ receptor, muscle AChR, P/Q- and N-type VGCC, neuronal ganglionic AChR, GFAP, ITPR1; AMPA receptor, NIF	Chest x-ray, chest CT with contrast PET	Multiple biomarkers reported but lack high enough specificity and sensitivity for current clinical practice	Environmental factors such as smoking history important in risk assessment
Testicular: germ cell/seminoma	**High risk:** Ma2 alone, KLHL11	Testicular US PET (for mediastinal, extra scrotal metastases)	α-Fetoprotein Human chorionic gonadotrophin	NA
Teratoma	**High risk:** NMDA receptor (NR1) **Low risk:** GFAP, AQP4	Pelvic CT Pelvic MRI Vaginal US	Generally negative	FDG-PET not recommended—teratomas show little or no FDG uptake
Ovarian carcinoma	**High risk:** PCA-1 (Yo) **Low risk:** Ma2, recoverin, P/Q- and N-type VGCC, GFAP, ARHGAP26 (GRAF1)	CT MRI pelvis PET	CA 125 (79%)	If PCA-1 positive but cancer workup negative, consider diagnostic laparoscopy.
Müllerian duct	**High risk:** PCA-1 (Yo)	CT MRI pelvis PET	NA	NA
Endometrial/cervical	**Low risk:** recoverin, P/Q- and N-type VGCC	Hysteroscopy Cervical smear, colposcopy	NA	NA
Gastrointestinal	**High risk:** PCA-1 (Yo) in men **Low risk:** neuronal ganglionic AChR, ARHGAP26 (GRAF1)	Upper and lower gastrointestinal endoscopy CT abdomen	CEA	Rarely associated with paraneoplastic disorders
Hematologic including Hodgkin lymphoma	**Low risk:** anti–Ta, anti-Ma2, α1 subunit GlyR, DPPX GFAP (rare), ITPR1, ARHGAP26 (GRAF1), α1 subunit GlyR **High risk:** PCA type Tr (delta/notch-like epidermal growth factor-related receptor); mGluR1, mGluR5	Chest x-ray, PET, MRI, and CT	CBC, bone marrow biopsy, blood smear, immunophenotyping (flow cytometry), β_2 microglobulin, serum creatinine, lactate dehydrogenase	NA
Thymoma	**High risk:** ANNA-1 (Hu), CRMP-5-IgG, LGI1[+] CASPR2, AMPA receptor **Low risk:** GAD65, AQP4-IgG, neuronal ganglionic AChR, muscle AChR, α1 subunit GlyR, LGI1, CASPR2, $GABA_A$ receptor	Chest CT with contrast	NA	NA
Neuroendocrine, Merkel cell, neuroblastoma, other	**High risk:** ANNA-1 (Hu)—especially children, NF-L **Low risk:** $GABA_B$ receptor	CT PET	Considerations: chromogranin A, NSE, u-5HIAA, plasma gastrin, insulin, glucagon, somatostatin, VIP, PP, others (plasma calcitonin, GHRH, IGF1, ACTH, PTH-rp)	NA

TABLE 74.4 Diagnostic Evaluation for Cancer in Suspected Paraneoplastic Neurologic Disorders[a] *(continued)*

Cancer Type	Neural Ab Specificities Associated	Diagnostic Imaging Tests	Blood Tests/Tumor Biomarkers	Comments
Prostate	Low risk: mGluR1, neuronal ganglionic AChR	MRI	PSA	Rarely associated with paraneoplastic disorders
Bladder/urothelial	Low risk: GFAP (rare)	Cystoscopy	NA	Rarely associated with paraneoplastic disorders
Renal	Low risk: Ma2, PDE10A	Abdomen CT, renal US	NA	Rarely associated with paraneoplastic disorders

Abbreviations: Ab, antibody; AChR, acetylcholine receptor; ACTH, adrenocorticotropin; AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic; ANNA, anti-neuronal nuclear antibody; AQP, aquaporin; CA, cancer antigen; CAR, cancer-associated retinopathy; CASPR2, contactin-associated protein 2; CBC, complete blood count; CRMP, collapsin-response mediator protein; CT, computed tomography; DPPX, dipeptidyl-peptidase-like protein 6; ER, estrogen receptor; FDG, fluorodeoxyglucose; $GABA_A$, γ aminobutyric acid type A; $GABA_B$, γ-aminobutyric acid type B; GAD65, glutamic acid decarboxylase, 65 kDa isoform; GFAP, glial fibrillary acidic protein; GHRH, growth hormone–releasing hormone; GlyR, glycine receptor; HER2, human epidermal growth factor receptor-2; IGF1, insulin-like growth factor 1; IgG, immunoglobulin G; ITPR1, inositol triphosphate receptor-1; KLHL11, Kelch-like protein 11; LGI1, leucine-rich glioma–inactivated protein 1; MAP1B, microtubule associated protein 1B; mGluR1, metabotropic glutamate receptor 1; mGluR5, metabotropic glutamate receptor 5; MRI, magnetic resonance imaging; NF-L, neurofilament light chain; NIF, neuronal intermediate filament; NMDA, *N*-methyl-D-aspartate; NSE, plasmatic neuron-specific enolase; PCA, Purkinje cell cytoplasmic antibody; PET, positron emission tomography; PP, pancreatic polypeptide; PR, progesterone receptor; PTH-rp, parathyroid-hormone like hormone; SOX, SRY-Box; u-5HIAA, urinary 5-hydroxy-indolacetic acid; US, ultrasound; VGCC, voltage-gated calcium channel; VIP, vasoactive intestinal peptide; BRCA1, breast cancer type 1 susceptibility protein; BRCA2, breast cancer type 2 susceptibility protein; Zic4, zinc finger protein of the cerebellum 4; CEA, carcinoma embyronic antigen; PSA, prostate specific antigen; PDE10A, phosphodiesterase 10A.

[a]High risk indicates >50% likelihood of malignancy, and low risk indicates <10% likelihood of malignancy (if antibody occurring in isolation).

cancer is identified, the general goal is to surgically remove the tumor in its entirety. Unfortunately, this generally does not result in significant clinical improvement. At the current time, we recommend standard oncologic therapy for such cases.

At the current time, there is no level 1 evidence or standardized guidelines to inform immunotherapeutic decisions in autoimmune encephalitis. The authors typically use a protocol divided into acute and chronic therapeutic phases. Before starting treatment, baseline neurologic and ancillary evaluations (eg, EEG, MRI, cognitive testing) should be performed to establish baseline parameters for objective treatment response monitoring. Antibody titers have limited use as a surrogate of clinical outcome.

Acute Therapy

For acute therapy, a trial of high-dose pulse intravenous or oral corticosteroids therapy is usually the first treatment tried. The IVIG may be used in patients who are unlikely to tolerate corticosteroids or are at risk for diabetes. Typical treatment protocols are outlined in Table 74.5. In patients with limited early responses to steroids, plasma exchange can be given as every other day exchanges (five to seven treatments) for 10 to 14 days. If IVIG is the primary treatment used, a weekly infusion of 0.4 to 1 g/kg can be used, or alternatively, 3 to 5 consecutive days on a monthly basis.

After the initial trial of therapy, the patient should be reevaluated to objectively determine the response to immunotherapy. If a rapid series of trials of immunotherapy are not beneficial in an acutely ill hospitalized patient with a well-characterized antibody-mediated encephalitis or meningitis, steroid or IVIG therapy should be continued, and an immunosuppressant (such as rituximab or cyclophosphamide) should be introduced early. In addition, therapeutic levels of antiepileptic drugs and supportive therapy for weeks to months are required. Supportive therapies will be required in an intensive care unit setting. This scenario is particularly relevant for patients with NMDAR encephalitis, who frequently require months of supportive care in addition to immunosuppression. In the author's experience, patients with isolated meningitis of unknown cause are generally treatable with corticosteroids and slow taper, once infectious causes and cancer have been excluded. Rituximab and corticosteroids tend to be used first line for the treatment of IgG4-related meningitis.

Chronic Therapy

Objective improvements should prompt consideration of maintenance immunotherapy over the longer term particularly if symptoms relapse on withdrawal of short-term acute therapies. Medium- (6 mo to 1 y) to long-term therapy (>1 y) with corticosteroids or IVIG is sometimes required, but the overall goal is for the eventual discontinuation of these. Oral immunosuppressants such as azathioprine or mycophenolate mofetil are useful to permit elimination of steroids or IVIG, where longer term treatment is planned (due to a prior relapse or patient known to be at risk for relapse). In the authors' practice, the interval between infusions of intravenous methylprednisolone or IVIG is extended over a period of 4 to 6 months from weekly to fortnightly, every 3 weeks, and then monthly, and eventual discontinuation. A faster taper of intravenous therapy can result in a relapse. When daily oral prednisone is being used, a slow reduction from 60-mg prednisone by 10 mg per month is preferable, with the last 10 mg being eliminated by 1 mg/mo. Some overlap of treatment with corticosteroid or IVIG and an oral long-term immunosuppressant is needed (a minimum of 12 wk for azathioprine and 8 wk for mycophenolate mofetil). Nonetheless, some patients remain dependent on corticosteroids or IVIG, despite appropriate dosing of oral long-term immunosuppression. Rituximab and cyclophosphamide can be considered as chronic therapies in patients who required these agents during the acute phase or patients who relapse and fail to respond to first-line therapies, although cyclophosphamide exposure should generally not exceed 18 months total, because of the risk of secondary hematologic malignancy. The authors recommend a trial of withdrawal of chronic therapy after 3 to 5 years, where no relapses have occurred.

For patients with paraneoplastic encephalitis where CNS injury is presumed to be predominantly cytotoxic T cell mediated (eg, Purkinje cell cytoplasmic antibody 1–associated cerebellar ataxia, ANNA-1–associated limbic encephalitis), with evidence of continuing neurologic deterioration, the authors tend to treat as early as possible with 12 weeks of intravenous methylprednisolone and initiate 6 to 12 months of oral or intravenous cyclophosphamide (see Table 74.5).

Emerging therapies also warrant consideration, especially in treatment refractory cases. In one study, patients with rituximab-refractory autoimmune encephalitis treated with tocilizumab (anti–interleukin 6) had better long-term outcomes compared

TABLE 74.5 Acute and Maintenance Immunotherapies for Autoimmune Encephalitis and Meningitis[a]

Therapy	Route/Dose/ Frequency	Monitoring/Other Recommendations	Mechanism of Action	Major Side Effects
Methylprednisolone (IVMP)	IV: 1,000 mg, daily for 3 consecutive days then once weekly for 5-11 wk	Trimethoprim/sulfamethoxazole (Bactrim DS) one tablet 3 times per week for *Pneumocystis carinii* prophylaxis. If allergic to sulfa, alternatives include dapsone 50 mg orally daily or pyrimethamine 50 mg orally weekly or leucovorin 25 mg orally weekly or atovaquone 1500mg orally daily or aerosolized pentamidine 300 mg every 4 wk. Proton-pump inhibitor (omeprazole) or H2 inhibitor (ranitidine) for gastrointestinal prophylaxis; calcium 1,500 mg and vitamin D 800 U daily	Inhibition of NF-κB, critical for the synthesis of cytokines/other components of the immune response pathway reduction in both T-cell and B-cell proliferation	Immunodeficiency, hyperglycemia and diabetogenesis, osteoporosis, avascular necrosis (hip or other joints), fat redistribution and weight gain, muscle breakdown, gastrointestinal ulcers, and memory and attention deficits. Prolonged usage (>1 wk) is also associated with adrenal suppression and atrophy of the adrenal glands, which may take months to recover.
IVIG	0.4 g/kg daily for 3 d followed by 0.4 g/kg every week for 5-11 wk	Check total immunoglobulin (Ig) and Ig isotypes to *exclude selective IgA deficiency*. Use with caution in patients with renal impairment or a history of thrombotic events.	Precise mechanism(s) of action not established: Include binding of anti-idiotypic antibodies to pathogenic antibodies, inhibition of the complement cascade, or increased degradation of existing autoantibodies.	Headache, infusion reactions, autoimmune hemolytic anemia, aseptic meningitis, deep venous thromboses, pulmonary emboli, acute tubular necrosis, renal failure, and pulmonary edema
Plasma exchange	Three to six plasma exchanges over consecutive or alternating days via a large-bore catheter	Administered in conjunction with other immunotherapies that are aimed at suppressing autoantibody production. The notable exception to this is GBS, which is a monophasic disorder and for which plasmapheresis is considered first line.	Removal of large molecular weight entities, including the antibody compartment and inflammatory cytokines and immune complexes while preserving the other components of the blood.	Central line infections, pneumothorax at line placement, hypotension
Rituximab (also consider ocrelizumab)	IV: 2 × 1,000 mg 14 d apart or 4 weekly doses of 375 mg/m^2, each cycle can be given routinely every 6 mo without monitoring of CD20/CD19 counts or by dosing as soon as CD20/CD19 >1%.	Baseline and follow-up HBV serology; baseline and monthly CBC; monthly consider CD20/CD19 B cells starting immediately postinfusion; if CD20/CD19 count exceeds 1% of total lymphocytes, redose with rituximab. If suppression of CD20/CD19 count does not occur, consider switching to alternative. Monitor immunoglobulins yearly. Premedicate with acetaminophen and an antihistamine.	Depletion of the B-cell compartment by promoting B-cell auto-apoptosis, complement-mediated cytotoxicity, and antibody-mediated cytotoxicity. Note: CD20 is not expressed on B-cell progenitors in the bone marrow (which allows for repopulation following rituximab therapy) or following terminal B-cell differentiation into the antibody-secreting lineages (plasmablasts and plasma cells).	Significant reactions can include infusion reactions, which may include edema, hypertension, fever, fatigue, chills, headache, insomnia, rash, pruritus, nausea, diarrhea, cytopenias, neutropenic fever, angioedema, bronchospasm, urticaria, and, in more severe cases, myocardial infarction, ventricular fibrillation, cardiogenic shock, and/or anaphylactic shock. Reactivation of hepatitis B causing fulminant hepatitis or latent tuberculosis may be fatal. Rarely, viral reactivation has been associated with rituximab, including JC virus which can cause PML.

TABLE 74.5 Acute and Maintenance Immunotherapies for Autoimmune Encephalitis and Meningitis[a] *(continued)*

Therapy	Route/Dose/ Frequency	Monitoring/Other Recommendations	Mechanism of Action	Major Side Effects
Cyclophosphamide	IV: 500-1,000 mg/m^2 monthly for 3-6 mo Orally: 1-2 mg/kg in morning	The blood count nadir typically occurs between 8 and 14 d postinfusion. For WBC nadir of <3,000 cells/mm^3 of blood but >1,500 cells/mm^3 of blood, reduce next dose by 25%. For WBC nadir <1,500 cells/mm^3 of blood or absolute neutrophil count <500 cells/mm^3 of blood, reduce dose by 50%. For hemoglobin <8.3 g/dL, the dose should be reduced by 25%. For platelet counts <80,000 cells/mm^3 of blood, reduce dose by 50%. For serum Cr <2.0 mg/dL, the standard dose may be used. For serum Cr 2.0 mg/dL, give 75% of standard dose. For serum Cr >3.5 mg/dL, give 50% of the standard dose. For serum bilirubin 3.1-5 mg/dL or transaminases elevation, 75% of the dose should be administered. For serum bilirubin >5 mg/mL, cyclophosphamide should not be used. Follow UA every month. Severe, potentially fatal acute hemorrhagic cystitis may occur. Therefore, mesna prophylaxis and prehydration are important.	Alkylating agent that causes irreversible DNA cross-linking during cell replication, leading to apoptosis	Marrow suppression, hemorrhagic cystitis, infertility, cardiotoxicity, and an increased risk of secondary malignancies including bladder carcinoma and acute myeloid leukemia. alopecia (40%-60%): Hair will usually regrow, although it may be a different color and/or texture. Hair loss usually begins 3-6 wk after the start of therapy. Sterility: Cyclophosphamide may cause sterility through interfering with oogenesis and spermatogenesis. This may be irreversible in some patients. Nausea and vomiting: This usually begins 6-10 h after administration; anorexia, diarrhea, mucositis, and stomatitis may also occur.
Tocilizumab (also consider satralizumab)	8 mg/kg administered for two or more cycles in regular 1-mo intervals	Consider in rituximab/cyclophosphamide refractory encephalitis/meningitis. Screening for latent TB infection and chronic HBV infection	Blocks IL-6 mediated proinflammatory signaling, reduction in APC survival; reduction in proinflammatory B-cell activity	Hypersensitivity reactions, including anaphylaxis. and increased risk of infection, including opportunistic infections
Bortezomib	IV: 1.3 mg/m^2 per dose twice-weekly for 2 wk, followed by a 10-d rest period (21-d treatment cycle) for a maximum of eight treatment cycles	Monitor CBC and LFTs regularly throughout treatment. Use a lower starting dose for patients with moderate or severe hepatic impairment. Women should avoid becoming pregnant. Patients with preexisting severe neuropathy should be treated only after careful risk-benefit assessment. Valacyclovir prophylaxis (500 mg orally per day) required to prevent against disseminated zoster infection	Binds catalytic site of 26S proteasome, reduces autoantibody titers, enhanced apoptosis of APC	Most commonly reported adverse reactions (incidence ≥20%) in clinical studies include nausea, diarrhea, thrombocytopenia, neutropenia, peripheral neuropathy, fatigue, neuralgia, anemia, leukopenia, constipation, vomiting, lymphopenia, rash, pyrexia, and anorexia. Also reported arrhythmia, heart failure, PRES, thrombocytopenia, hepatic toxicity, thromboses.
Azathioprine (+ prednisone)	Orally: 2-3 mg/kg/d	Initial: TPMT activity assay, CBC, Cr, LFTs. Periodic: Target MCV↑ ≥5 fL weekly CBC, LFTs for 1 mo, monthly for 6 mo, and then twice per year; maintain absolute neutrophil counts >1,000 cells/μL.	Inhibition of purine (and therefore DNA) synthesis affects rapidly proliferating cells—especially effector B and T cells and promoting T-cell apoptosis upon costimulation.	Hypersensitivity reactions, fever, malaise, myalgias, nausea/vomiting, and diarrhea are common. Low WBC count Leukopenia, anemia, thrombocytopenia, liver toxicity or pancreatitis may occur. Rarer complications include infection, skin neoplasia, and lymphoma. Limit sun and ultraviolet light exposure

(table continues on page 770)

TABLE 74.5 Acute and Maintenance Immunotherapies for Autoimmune Encephalitis and Meningitis[a] *(continued)*

Therapy	Route/Dose/ Frequency	Monitoring/Other Recommendations	Mechanism of Action	Major Side Effects
Mycophenolate mofetil (+ prednisone)	Orally: 1,000-3,000 mg/d	Initial: CBC, Cr, and LFTs. Periodic: ALC target of 1,000-1,500 cells/μL; weekly CBC, LFT for 1 mo, monthly for 6 mo, and then twice per year Drug levels can be measured to avoid undertreatment or toxicity. The level of mycophenolic glucuronide (an enzyme that metabolizes mycophenolate) may be indicative of risk for drug toxicity or a subtherapeutic drug level.	Inhibits B- and T-cell proliferation due to the fact that these lymphocytes lack an alternative nucleotide salvage pathway, thereby causing T-cell apoptosis and reducing B-cell antibody production	Gastrointestinal, including diarrhea, dyspepsia, and nausea. Other common side effects include hypertension and edema. Serious side effects, although rare, include CNS lymphoma or other malignancies and opportunistic infection. Thrombocytopenia, leukopenia, or neutropenia can occur. Mycophenolate is associated with an increased risk of congenital malformations and first trimester pregnancy loss.
Prednisone	Orally: 15-30 mg daily dose; taper after 1 y	See IVMP.	See IVMP.	See IVMP.
Calcineurin inhibitors CsA Tacrolimus	Orally: started at 2-5 mg/kg/d twice daily Orally: 0.15-0.30 mg/kg two divided oral doses	Narrow therapeutic window. Frequent monitoring of CsA/ tacrolimus blood concentrations is necessary to minimize side effects and optimize efficacy of immunosuppression. Frequent CBC and Cr.	Both cyclosporine and tacrolimus prevent the activity of calcineurin, thereby reducing IL-2 production and T-cell activation. CsA has also been shown to inhibit B-cell proliferation and activation.	Mild gingival hyperplasia, hirsutism, and tremor to potentially severe hypertension with posterior reversible encephalopathy syndrome, nephrotoxicity, neurotoxicity, and malignancy. Tacrolimus, which has a very similar mechanism of action to CsA, appears to be better tolerated, with milder reported side effects.
Methotrexate (+ prednisone)	Orally:15-25 mg weekly	Check LFTs every 3 mo; recommend 1 mg of folate supplementation; avoid NSAIDs. Avoid if Cr >3 mg/dL. Monitor CBC monthly.	Folic acid analog that inhibits purine and pyrimidine synthesis, thus interrupting DNA replication and consequently cell proliferation	Gastrointestinal distress, fatigue, neutropenia, and rarely hepatotoxicity

Abbreviations: ALC, absolute lymphocyte count; ALT, alanine aminotransferase; APC, antigen-presenting cell; CBC, complete blood count; CD, cluster of differentiation; CNS, central nervous system; Cr, creatinine; CsA, cyclosporin A; GBS, Guillain-Barré syndrome; HBV, hepatitis B virus; IL, interleukin; IV, intravenous; IVIG, intravenous immunoglobulin; IVMP, intravenous methylprednisolone; JC, John Cunningham; LFTs, liver function tests; MCV, mean corpuscular volume; NF-κB, nuclear factor kappa-light-chain-enhancer of activated B cells; NSAID, nonsteroidal anti-inflammatory drug; PML, progressive multifocal leukoencephalopathy; PRES, posterior reversible encephalopathy syndrome; TB, tuberculosis; TPMT, thiopurine methyltransferase; UA, urinalysis; WBC, white blood cell.
[a]Female patients of reproductive potential should have a negative pregnancy test immediately before therapy, and the test should be repeated 8-10 d later. Pregnancy tests should be repeated during routine follow-up visits. Acceptable forms of contraception should be used during treatment and for 6 wk after therapy is discontinued.

with those patients who continued rituximab or received no subsequent treatment. The plasma cell-depleting proteasome inhibitor bortezomib has resulted in clinical improvement in otherwise treatment-refractory NMDAR encephalitis. Other promising agents include inebilizumab (targets CD19 and thus allows targeting of plasmablasts) and anakinra (targets the proinflammatory cytokine, interleukin 1).

Careful monitoring for side effects of long-term immunotherapy is critical. Surveillance include monitoring of blood counts, liver, and renal function. Where azathioprine is the oral agent chosen, thiopurine methyltransferase deficiency needs to be eliminated prior to treatment initiation. Experience suggests that monitoring for a rise of mean corpuscular volume of at least 5 points from baseline is an indicator of efficacy.

Patients on glucocorticoids must also take elemental calcium 1,500 mg/d and vitamin D 1,000 IU/d, either dietary or in supplement form. Deterioration of bone mineral density may occur shortly after initiating steroids. Baseline and follow-up bone densitometry and bisphosphonate treatment should be considered in those needing more than 3 months of steroid treatment. *Pneumocystis jiroveci* pneumonia prophylaxis should consist of trimethoprim/sulfamethoxazole one double-strength tablet 3 times per week (or one single-strength tablet daily) for patients on chronic corticosteroids or azathioprine. Alternatives for sulfa-allergic patients include daily oral atovaquone 1,500 mg/d.

PREDICTIVE SCORES

Application of predictive scores in neurologic practice could optimize utilization of neural autoantibody evaluation and immunotherapeutic trials. To aid with this selection, a composite score was formulated: Antibody Prevalence in Epilepsy and Encephalopathy (APE2). The APE2 score is based on clinical features suggestive of autoimmune encephalitis and initial neurologic assessment (Table 74.6). For prediction of neural-specific antibody seropositivity among patients presenting with encephalopathy, an APE2 score ≥4 was 99% sensitive and 93% specific. The Response to Immunotherapy in Epilepsy and Encephalopathy score (see Table 74.6) also incorporates

TABLE 74.6 Antibody Prevalence in Epilepsy and Encephalopathy (APE2) Score and Response to Immunotherapy in Epilepsy and Encephalopathy (RITE2) Score[a]

APE2 Score	Value	RITE2 Score	Value
New-onset, rapidly progressive mental status changes that developed over 1-6 wk or new-onset seizure activity (within 1 y of evaluation)	(+1)	New-onset, rapidly progressive mental status changes that developed over 1-6 wk or new-onset seizure activity (within 1 y of evaluation)	(+1)
Neuropsychiatric changes; agitation, aggressiveness, emotional lability	(+1)	Neuropsychiatric changes; agitation, aggressiveness, emotional labiality	(+1)
Autonomic dysfunction (sustained atrial tachycardia or bradycardia, orthostatic hypotension, hyperhidrosis, persistently labile blood pressure, ventricular tachycardia, cardiac asystole, or gastrointestinal dysmotility)[a]	(+1)	Autonomic dysfunction (sustained atrial tachycardia or bradycardia, orthostatic hypotension, hyperhidrosis, persistently labile blood pressure, ventricular tachycardia, cardiac asystole or gastrointestinal dysmotility)[a]	(+1)
Viral prodrome (rhinorrhea, sore throat, low-grade fever) to be scored in the absence of underlying systemic neoplasm within 5 y of neurologic symptom onset	(+2)	Viral prodrome (rhinorrhea, sore throat, low-grade fever) only to be scored in the absence of underlying neoplasm within 5 y of neurologic symptom onset	(+2)
Faciobrachial dystonic seizures	(+3)	Faciobrachial dystonic seizures	(+3)
Facial dyskinesias, to be scored in the absence of faciobrachial dystonic seizures	(+2)	Facial dyskinesias, to be scored in the absence of faciobrachial dystonic seizures	(+2)
Seizure refractory to at least to two antiseizure medications	(+2)	Seizure refractory to at least to two antiseizure medications	(+2)
CSF findings consistent with inflammation (elevated CSF protein >50 mg/dL and/or lymphocytic pleocytosis >5 cells/μL, if the total number of CSF RBC is <1,000 cells/μL)	(+2)	CSF findings consistent with inflammation (elevated CSF protein > 50 mg/dL and/or lymphocytic pleocytosis >5 cells/μL, if the total number of CSF RBC is <1,000 cells/μL)	(+2)
Brain MRI suggesting encephalitis (T2/FLAIR hyperintensity restricted to one or both medial temporal lobes or multifocal in gray matter, white matter, or both compatible with demyelination or inflammation)	(+2)	Brain MRI suggesting encephalitis (T2/FLAIR hyperintensity restricted to one or both medial temporal lobes, or multifocal in gray matter, white matter, or both compatible with demyelination or inflammation)	(+2)
Systemic neoplasm diagnosed within 5 y of neurologic symptom onset (excluding cutaneous squamous cell carcinoma, basal cell carcinoma, brain tumor, cancer with brain metastasis)	(+2)	Systemic neoplasm diagnosed within 5 y of neurologic symptom onset (excluding cutaneous squamous cell carcinoma, basal cell carcinoma, brain tumor, cancer with brain metastasis)	(+2)
	Total (max: 18)	Immunotherapy initiated within 6 mo of symptom onset	(+2)
		Neural plasma membrane autoantibody detected (NMDAR, $GABA_A$ receptor, $GABA_B$ receptor, AMPAR, DPPX, mGluR1, mGluR5, LGI1, CASPR2, neurexin-3α, MOG)	(+2)
			Total (max: 22)

Abbreviations: AMPAR, amino-3-hydroxy-5-methyl-4-isoxazolepropionic receptor; CASPR2, contactin-associated protein 2; CSF, cerebrospinal fluid; DPPX, dipeptidyl-peptidase-like protein 6; FLAIR, fluid-attenuated inversion recovery; $GABA_A$, γ-aminobutyric acid type A; $GABA_B$, γ-aminobutyric acid type B; LGI1, leucine-rich glioma–inactivated protein 1; mGluR1, metabotropic glutamate receptor 1; mGluR5, metabotropic glutamate receptor 5; MOG, myelin oligodendrocyte glycoprotein; MRI, magnetic resonance imaging; NMDAR, *N*-methyl-D-aspartate receptor; RBC, red blood cell.

[a]Scored only if no history of autonomic dysfunction prior to onset of suspected autoimmune syndrome and the autonomic dysfunction not attributable to medications, hypovolemia, plasmapheresis, or infection.

two independent predictors of favorable outcome: initiation of immunotherapy within 6 months of symptom onset and presence of neural-specific cell surface autoantibodies in serum or CSF. For encephalopathy patients receiving first-line immunotherapy trials, Response to Immunotherapy in Epilepsy and Encephalopathy score ≥7 had 96% sensitivity and 86% specificity for favorable response to initial immunotherapy. Specifically for NMDAR encephalitis, a 5-point grading system can also be used: NMDAR Encephalitis One-Year Functional Status score.

OUTCOME

Autoimmune encephalitis can be severe with mortality rates of up to 20%. As a general rule, those with antibodies to cell-surface antigens (eg, NMDAR, LGI1, $GABA_A$ receptor) have better prognosis than those with antibodies reactive with intracellular targets (eg, ANNA-1 [anti-Hu], Ma2). A notable exception is autoimmune GFAP astrocytopathy that responds well to steroids and often has a favorable long-term outcome. In those with antibodies to cell surface targets, a severe initial presentation (such as coma or status epilepticus) does not reliably predict a bad long-term outcome, and a poor prognosis should not be prematurely considered. Indeed, a slow and prolonged recovery with a favorable outcome is often achievable with aggressive immunotherapy. In NMDAR encephalitis, improvement can continue up to 18 months after onset. In NMDAR encephalitis, the addition of second-line immunotherapy (rituximab or cyclophosphamide) has been associated with better outcomes than first-line treatments alone (steroids, IVIG, plasma exchange), where no improvement was observed after those initial treatments.

In patients with LGI1 encephalitis, seizures and cognitive symptoms tend to respond quickly and often completely to immunotherapy (corticosteroids and plasma exchange in particular), but cognitive deficits may take longer to recover. In addition, early treatment (within a few weeks of onset) portends better recovery.

Neurosarcoidosis 75

Siddharama Pawate and Barney J. Stern

KEY POINTS

1. Optimal diagnosis of systemic sarcoidosis and neurosarcoidosis typically includes pathologic documentation of granulomatous inflammation.
2. The diagnosis of sarcoidosis and neurosarcoidosis is most secure if infection and malignancy are excluded.
3. Neurosarcoidosis patients with progressive or relapsing disease are best managed with low-dose corticosteroid and adjunct immunosuppressive drugs.

INTRODUCTION

Sarcoidosis is a multisystemic inflammatory disease of unknown etiology, characterized histopathologically by noncaseating granulomas that do not show the presence of infectious organisms. The pathogenesis is presumed to be immune-mediated and directed against as yet unidentified antigen(s).

Intrathoracic sarcoidosis (pulmonary sarcoidosis and mediastinal lymphadenopathy) occurs in 9 out of 10 patients. Neurologic involvement due to sarcoidosis, termed *neurosarcoidosis*, occurs in 10% to 15% of patients and can affect any part of the central or peripheral nervous system (PNS), resulting in highly varied clinical manifestations. Isolated neurosarcoidosis without systemic involvement is thought to represent as many as 17% of neurosarcoidosis patients.

EPIDEMIOLOGY

Sarcoidosis can be asymptomatic in a substantial proportion of patients, making the determination of its true incidence and prevalence difficult. It is a global disease, with available studies reporting an incidence ranging from 0.2 per 100,000 people in Brazil to 19 per 100,000 people in Sweden. In the United States, the incidence of sarcoidosis is estimated at 3 to 10 per 100,000 per year among Caucasians and 35 to 80 per 100,000 per year among African Americans. The majority of patients (70%) are between the ages of 25 and 45 years at diagnosis, and in women in Europe and Japan, there is a second peak incidence after age 50 years.

Genetic as well as environmental factors influence sarcoidosis. First- and second-degree relatives of patients with sarcoidosis, but not spouses, have a fivefold higher risk, indicating a genetic predisposition. The study of genes associated with sarcoidosis is in its infancy. Given the critical role major histocompatibility plays in antigen presentation, it is not surprising that a majority of the genes associated with sarcoidosis to date are predominantly those of human leukocyte alloantigen regions, and different human leukocyte alloantigen regions associate with different clinical phenotypes of sarcoidosis. Genome-wide association studies have also implicated inflammatory mediators such as toll-like receptor 4, transforming growth factor β, and tumor necrosis factor (TNF). Occupational exposure to microbe-rich environments such as mold and mildew, insecticides, and pesticides resulted in a higher risk. Although sarcoidosis is not an infectious disease, an exaggerated immune response to antigens is thought to be the likely mechanism, and thus, microbial exposure may play an indirect role. Cigarette smokers have a risk of sarcoidosis one-fifth of nonsmokers, presumably due to the immunosuppressive effect of tobacco exposure.

PATHOBIOLOGY

Sarcoidosis is mediated primarily by $CD4^+$ T helper 1 cells and mononuclear phagocytes, with participation of numerous cytokines and chemokines that include interleukins, adhesion molecules, interferon-γ, TNF-α, and transforming growth factor β. Lesions may affect any organ, especially lungs, lymph nodes, skin, bones, eyes, and salivary glands. When nervous system disease complicates systemic sarcoidosis, it usually does so within 2 years of onset.

In the central nervous system (CNS), sarcoid granulomas most often involve the meninges, especially at the base of the brain, with secondary infiltration of cranial nerves and obstruction of cerebrospinal fluid (CSF) flow. Lesions tend to be perivascular and thereby may extend into the parenchyma, frequently affecting the hypothalamus and, less often, other CNS structures, including the spinal cord. Granulomas also occur in peripheral nerves and muscle.

CLINICAL MANIFESTATIONS

The clinical manifestations of neurosarcoidosis are heterogeneous as granulomatous inflammation may affect any anatomic substrate pertaining to the meninges, cranial nerves, brain, spinal cord, meninges, peripheral nerves, and muscles resulting in diverse clinical forms of the disease.

Cranial Nerves

Unilateral or bilateral lower motor neuron facial nerve palsy is the most common cranial nerve presentation. A peripheral facial nerve palsy can herald sarcoidosis, which may remain unrecognized for years. Other relatively frequent cranial neuropathies are optic neuropathy and vestibulocochlear nerve dysfunction, which can be unilateral or bilateral. Optic nerve involvement (Fig. 75.1A) typically presents as a subacute or chronic optic neuritis. Vision loss can also be rarely due to extrinsic compression of the optic nerve from granulomatous inflammation.

Isolated hearing loss or vertigo due to selective vestibulocochlear nerve involvement can occur, and bilateral sensorineural hearing loss should prompt an evaluation for neurosarcoidosis. Other cranial nerves are involved less frequently. Multiple cranial neuropathies can occur.

Meninges

Meningeal involvement can present as a subacute lymphocytic meningitis, with headache and variable nuchal rigidity with or without fever. Chronic meningitis frequently occurs and may or may not be associated with headache. Leptomeningeal involvement is typical (Fig. 75.1B), but dural involvement (pachymeningitis) can also occur (Fig. 75.1C). Hydrocephalus, either communicating or noncommunicating, can complicate meningitis. Occasionally, a dural inflammatory mass mimics a meningioma.

Brain Parenchyma

The manifestations of granulomas within the brain parenchyma depend on the location and size of the lesions. Figure 75.1D shows a left temporal lesion suspicious for a neoplasm that was intensely fluorodeoxyglucose avid (Fig. 75.1E). Small subcortical or periventricular white matter lesions may be asymptomatic. Seizures are a fairly common presentation. Neurosarcoidosis has a predilection for the hypothalamus, resulting in a range of disturbances including hypothyroidism, hypogonadism, and resetting of the "osmostat" or the syndrome of inappropriate antidiuretic hormone.

FIGURE 75.1 **A:** Sarcoid optic neuropathy. A brain magnetic resonance imaging shows thickening and intense contrast enhancement of the right optic nerve *(arrow)*, consistent with an infiltrating process. The resolution of contrast enhancement after steroid therapy (not shown) made it unlikely to be a neoplastic process. **B,C:** Meningeal sarcoidosis. **B:** Sagittal postcontrast T1 images show extensive leptomeningeal enhancement in the posterior fossa as well as in the frontal lobe *(arrows)*. **C:** Coronal postcontrast T1 images show thickening and enhancement of the dura in the tentorium. **D,E:** Parenchymal sarcoidosis. Axial postcontrast magnetic resonance imaging images show a contrast-enhancing lesion in the left temporal lobe in this patient with new-onset seizures, concerning for a neoplasm as fludeoxyglucose positron emission tomography showed the lesion to be intensely fluorodeoxyglucose avid. However, the patient had biopsy-proven lung sarcoidosis and was treated with high-dose steroids, and the lesion resolved. **F,G:** Spinal cord sarcoidosis. **F:** T2 sequence showed a longitudinally extensive hyperintense lesion associated with cord swelling *(arrow)*. **G:** The postcontrast T1 sequence showed enhancement *(arrow)* of the spinal cord as well as the overlying meninges posteriorly.

Spinal Cord

Patients may have gradually worsening myelopathic (typically, a combination of motor, sensory, and bladder/bowel manifestations) symptoms developing over months. A subpial intramedullary lesion is typical (Fig. 75.1F,G), but in up to half the patients, the overlying meninges are involved as well. The thoracic region is most commonly involved followed by cervical disease.

DIAGNOSIS

When patients with known, active systemic sarcoidosis present with neurologic symptoms, neurosarcoidosis is usually prominent in differential diagnostic considerations and if the initial evaluation points to neurosarcoidosis, a therapeutic trial with high-dose corticosteroids may be justified. Patients with no prior history of systemic sarcoidosis are more challenging and diagnosis requires a high index of suspicion.

Imaging provides a noninvasive way to look for evidence of granulomatous inflammation. Typically, patients will require brain and/or spine MRI (see Fig. 75.1). Parenchymal brain and spinal cord lesions are typically seen as T1-isointense, T2-hyperintense areas with variable gadolinium enhancement. Leptomeningeal involvement may not be apparent T1 or T2 sequences, but a contrasted T1 study often shows linear or nodular meningeal enhancement. For patients with contraindications to MRI, computed tomography (CT) is an option but has much lower sensitivity and specificity. Iodinated contrasted CT scans can sometimes highlight more lesions and meningeal involvement.

Systemic imaging is helpful to establish extraneural sarcoidosis and provide possible targets for biopsy. Chest CT is more sensitive than chest x-ray. Fluorodeoxyglucose positron emission tomography can help identify extrathoracic lesions amenable for biopsy.

Serologic and CSF testing is often used. CSF typically shows pleocytosis and increased protein as nonspecific markers of inflammation, and less commonly, decreased glucose. Serum and CSF angiotensin converting enzyme levels can be elevated in sarcoidosis but lack sensitivity and specificity. Most authorities do not recommend relying on these levels for neurosarcoidosis diagnosis.

Ultimately, histopathology is necessary for confident diagnosis. This was reflected in consensus definition and diagnostic criteria issued by the Neurosarcoidosis Consortium Consensus Group. They proposed criteria to stratify diagnostic probability of neurosarcoidosis into definite, probable, and possible neurosarcoidosis (Table 75.1).

In PNS sarcoidosis, clinical, nerve conduction studies, and electromyogram findings are nonspecific and often indistinguishable from primary immune-mediated neuromuscular disorders (eg, polymyositis or chronic inflammatory demyelinating polyneuropathy), which respond to corticosteroids and other immunotherapies used for sarcoidosis. Thus, histologic confirmation of the affected tissue or evidence of systemic disease is required for a definite or probable diagnosis of peripheral neurosarcoidosis, respectively. Fortunately, in most cases of muscle and nerve involvement, the affected tissue is more readily accessible for biopsy in contrast to patients with CNS disease.

Conditions that can present similarly to sarcoidosis include CNS neoplasms such as gliomas or lymphoma; demyelinating disease; and fungal, tuberculous, or bacterial infections. A detailed list of differential diagnosis considerations is presented in Table 75.2.

TABLE 75.1 Criteria for the Diagnosis of Neurosarcoidosis as Proposed by the Neurosarcoidosis Consortium Consensus Group[a,b]

Definite	Nervous system pathology is consistent with neurosarcoidosis. • Extraneural sarcoidosis is evident. • No extraneural sarcoidosis is evident (ie, isolated central nervous system sarcoidosis).
Probable	There is pathologic confirmation of systemic granulomatous disease consistent with sarcoidosis.
Possible	There is no pathologic confirmation of granulomatous disease.

[a]In patients whose clinical presentation and diagnostic evaluation suggests neurosarcoidosis as defined by the clinical manifestations and magnetic resonance imaging, cerebrospinal fluid, and/or electromyogram/nerve conduction study findings typical of granulomatous inflammation of the nervous system and rigorous exclusion of other causes, neurosarcoidosis can be diagnosed at three levels of certainty; definite, probable, and possible.
[b]Modified from Stern BJ, Royal W III, Gelfand JM, et al. Definition and consensus diagnostic criteria for neurosarcoidosis: from the Neurosarcoidosis Consortium Consensus Group. *JAMA Neurol.* 2018;75(12):1546-1553.

Magnetic Resonance Imaging Findings

A gadolinium-enhanced brain or spine magnetic resonance imaging (MRI) is the most important imaging modality to evaluate CNS sarcoidosis; it is highly sensitive but nonspecific. Granulomatous inflammation is associated with breakdown of the blood-brain barrier, causing enhancement of affected areas. Leptomeningeal enhancement occurs especially along the skull base. Dural thickening and enhancement can be focal or diffuse and may be hypointense on T2-weighted sequences. Cranial nerve enhancement may be seen. Intraparenchymal granulomas can be seen as subcortical white matter lesions mimicking multiple sclerosis or micro-ischemic lesions, or can involve the deep grey matter. Large solitary aggregations of granulomas can masquerade as neoplasms.

Cerebrospinal Fluid Findings

CSF findings are nonspecific but help establish the presence of intrathecal inflammation and rule out infectious and neoplastic processes. Nonspecific CSF markers of CNS inflammation (pleocytosis, elevated protein, hypoglycorrhachia, oligoclonal bands, and elevated immunoglobulin G index) are seen in overall in 50% to 70% of patients with neurosarcoidosis. CSF abnormalities are most likely in patients with leptomeningeal enhancement.

Peripheral Nervous System and Muscle Presentations

Symptomatic involvement of the PNS in sarcoidosis is rare, occurring in only 1% to 2% of patients with systemic disease. Granulomatous inflammation may result in vasculitis, infiltration, or direct compression of peripheral nerve and muscle fibers.

A small fiber neuropathy with sensory or autonomic nervous system symptoms can occur in patients with systemic sarcoidosis or neurosarcoidosis. Granulomas are not evident on skin biopsy analysis of small fiber terminals, and this manifestation can be considered a "parasarcoidosis" phenomenon, thought to be mediated by circulating inflammatory mediators.

TABLE 75.2 Selected Differential Diagnostic Considerations for Neurosarcoidosis

Category	Examples	Comments
Systemic and CNS Infections	Tuberculosis Atypical mycobacterium (very rare in the absence of prior neurosurgery or hardware) CNS fungal infections - coccidiomycosis, histoplasmosis, cryptococcus, sporotrichosis, blastomycosis Spirochetal infections – Neurosyphilis, neuroborreliosis (Lyme disease) Tropheryma (Neuro-Whipple's disease) Progressive multifocal leukoencephalopathy Parasitic infection (in the appropriate neuroimaging, CSF exam or epidemiological context)	Cultures, Serologies, PCR as appropriate to detect infectious organisms may help establish an infectious etiology.
Malignancy	Lymphoma (Primary CNS or Systemic with neurological involvement) CNS tumors (glioma, germ cell tumor, craniopharyngioma) Meningeal carcinomatosis	Histopathology will detect neoplasms.
Other Neuro-inflammatory Disorders	Histiocytosis (Erdheim-Chester disease) Multiple Sclerosis, especially tumefactive lesions Acute Disseminated Encephalomyelitis Neuromyelitis optica spectrum disorders CNS Vasculitis Autoimmune astrocytopathy with anti-GFAP antibodies Anti-MOG syndrome	Histopathology may help detect other etiologies. CT angiogram or conventional cerebral angiogram may be required when vasculitis is suspected. AQP4 or MOG antibodies may be detected in patients with NMOSD.
Neurologic Involvement from a Systemic Disorder	Systemic lupus erythematosus IgG4-related hypertrophic pachymeningitis Sjogren's syndrome Behcet's disease Vogt-Koyanagi-Harada disease Common variable immunodeficiency (CVID)	Clinical and rheumatologic criteria may help point to systemic inflammatory diseases. Histopathology is definitive for IgG4 related disease
Vascular	Dural arterio-venous fistula (brain or spinal cord) or other vascular malformations such as AVM Stroke	Clinical context and vascular imaging

Abbreviations: AQP4, Aquaporin 4; CNS, central nervous system; CSF, cerebrospinal fluid; CT, computed tomography; GFAP, glial fibrillary acidic protein; MOG, myelin oligodendrocyte glycoprotein; NMOSD, neuromyelitis optica spectrum disorder; PCR, polymerase chain reaction.

[a]Magnetic resonance imaging and cerebrospinal fluid studies are sensitive in detecting CNS pathology but do not differentiate between sarcoidosis, other immune mediated conditions, infectious and neoplastic etiologies. Thus additional studies are required to discern other possibilities as indicated by the clinical context.

Another common phenomenon attributed to parasarcoidosis is *brain fog*, an informal term patients use to describe cognitive difficulties in the absence of evident brain involvement in the disease.

MANAGEMENT

The clinical course of neurosarcoidosis varies widely and is difficult to predict. However, in general, about two-thirds of patients with neurosarcoidosis have a self-limited monophasic illness such as isolated facial nerve palsy or aseptic meningitis. In these patients, a short course of corticosteroids is usually beneficial. Those with more severe disease such as parenchymal, optic nerve, or spinal cord involvement require prolonged therapy. In the absence of randomized clinical trials to guide therapy, the treatment of neurosarcoidosis is based primarily on clinical experience and small clinical case series. A daily dose of 40 to 80 mg prednisone may be given for a few weeks and then slowly tapered, either to a lowest possible maintenance dose or, if possible, to discontinuation. Higher initial doses may be necessary in some patients. Severe presentations may require pulse dose corticosteroids (1 g intravenous methylprednisolone daily for 3-5 d), followed by a prolonged oral taper. The long-term use of corticosteroids is limited by their well-known toxicity, including hyperglycemia, weight gain, osteoporosis, risk of infection, epidural lipomatosis, etc. Therefore, "steroid-sparing agents" are typically used (**Table 75.3**). Anecdotally, reported adjunctive immunosuppressive treatment for refractory patients includes, but is not limited to, mycophenolate mofetil, azathioprine, methotrexate, cyclophosphamide, and rituximab. Infliximab, an anti-TNF monoclonal antibody, has emerged as an effective agent in the treatment of neurosarcoidosis that is refractory to other agents. Early infliximab treatment should be considered in patients with aggressive neurosarcoidosis.

The role of surgery is typically limited to biopsy. Hydrocephalus may require a ventriculoperitoneal shunt.

OUTCOMES

In general, the outcome of patients with neurosarcoidosis is favorable. As noted above, "mild" disease such as facial nerve palsy and aseptic meningitis typically recovers completely. In more severe cases, the extent of permanent CNS or PNS damage contributes to less than optimal clinical recovery. In some patients, clinical deficits may take significantly longer to recover than imaging findings.

TABLE 75.3 Agents Used in the Treatment of Neurosarcoidosis[a]

Agent	Dosage	Adverse Effects	Monitoring
Corticosteroids			
Prednisone	Start 40 mg/d or up to 1 mg/kg/d depending on severity, with aim to taper as fast as feasible to minimum required	Numerous side effects include effects on blood glucose, Cushing syndrome, fluid retention, gastrointestinal upset, osteoporosis, cataracts; with pulse steroids, a 1 in 10,000 chance of avascular hip necrosis (1 in 1000 after repeated courses)	Clinical monitoring
IV methylprednisolone pulse	Initial treatment of moderate to severe cases, 1000 mg/dfor 3-5 days, followed by transition to oral prednisone regimen above	Numerous side effects include effects on blood glucose, Cushing syndrome, fluid retention, gastrointestinal upset, osteoporosis, cataracts; with pulse steroids, avascular hip necrosis has a 1 in 10,000 chance (1 in 1000 after repeated courses)	Clinical monitoring
Steroid sparing agents			
Azathioprine	50-150 mg/d	Bone marrow suppression, gastrointestinal upset 1 in 300 whites are deficient in thiopurine methyltransferases, an enzyme that metabolizes azathioprine, and azathioprine should be avoided in them.	CBC with differential counts, liver functions monthly initially, then every 3-6 months; check thiopurine methyltransferase before initiation
Methotrexate	10-25 mg/wk along with folic acid 1 mg/d	Bone marrow suppression, gastrointestinal upset	CBC with differential counts liver functions every 4-6 weeks initially and once every 3-6 months after stabilized
Mycophenolate mofetil	1000-1500 mg 2 times a day	Gastrointestinal upset, headaches, leukopenia	CBC with differential counts every 6 weeks for 6 months, then every 3-6 months
Cyclophosphamide	Pulse dosing 500-750 mg/m2 IV every 4 weeks, typically for 6-9 months as 'induction' therapy	Hemorrhagic cystitis (can be avoided by careful hydration), leukopenia, infections	CBC with differential counts, urinalysis per infusion protocol
Rituximab	1000 mg IV infusion on day 1 and day 15, then 1000 mg every 6-8 months depending on CD19 counts	Well tolerated, opportunistic infections are a concern; after prolonged use, may require IgG repletion	Lymphocyte subsets to guide dosing or may dose once every 6 months scheduled
Anti-tumor necrosis factor therapy			
Infliximab	3-7 mg/kg IV infusions, week 0, 2, and 6, then every 4 to 6 weeks	Infusion reactions, central nervous system demyelination, opportunistic infections	Confirm the absence of tuberculosis before initiation
Adalimumab	40 mg subcutaneously every 2 weeks	Infusion reactions, central nervous system demyelination, opportunistic infections, injection site reactions	Confirm the absence of tuberculosis before initiation

Abbreviations: IV, intravenous; CBC, complete blood count; IgG, immunoglobulin G.

Essential Tremor 76

Elan D. Louis

KEY POINTS

1. Essential tremor (ET) is a chronic, progressive neurologic disease. The hallmark motor feature is a 4- to 12-Hz kinetic tremor that involves the arms and hands.
2. Tremor may eventually spread to involve the head (ie, the neck), voice, and jaw.
3. The ET patients have about a fourfold increased risk of developing incident Parkinson disease (PD), thereby developing what is referred to as *essential tremor–Parkinson disease* (ET-PD).
4. Recent years have witnessed an increasing appreciation of the presence of nonmotor features in ET patients, which may broadly be classed into cognitive, psychiatric, and sensory.
5. Controlled postmortem studies have revealed an array of degenerative changes in the cerebellar cortex.
6. β-Blockers (especially propranolol) and primidone, alone or in combination, are the most effective pharmacologic therapies. High-frequency thalamic stimulation markedly reduces the severity of the tremor and magnetic resonance imaging–guided focused ultrasound thalamotomy is another emerging surgical therapy.

INTRODUCTION

Essential tremor (ET) is a chronic, progressive neurologic disease. The hallmark motor feature is a 4- to 12-Hz kinetic tremor (tremor occurring during voluntary movements, such as writing or eating) that involves the arms and hands (Fig. 76.1). Tremor may eventually spread to involve the head (ie, the neck), voice, and jaw. Given the presence of etiologic, clinical, pharmacologic response profile, and pathologic heterogeneity, there is growing support for the notion that ET may be a family of diseases whose central defining feature is kinetic tremor of the arms and which might more accurately be referred to as *the essential tremors*.

EPIDEMIOLOGY

The ET is among the most prevalent adult-onset movement disorders, although it may occur at any age, and pediatric cases, with age of onset in the first decade of life have been reported. In a meta-analysis of data from 28 population-based prevalence studies in 19 countries, the pooled prevalence of ET across all ages was 0.9%. The prevalence increases markedly with age and especially with advanced age. In the meta-analysis, prevalence among persons aged 65 years and older was 4.6%, and in some studies, the prevalence among persons aged 95 years and older reached values in excess of 20%. The rate at which new ET cases arise (ie, the incidence rate) has been estimated as 619 per 100,000 person-years among individuals age 65 years and older; this incidence rises with age. Established risk factors for ET include older age and family history of ET.

ETIOLOGY

Both genetic and environmental (ie, toxic) factors are likely contributors to disease etiology. Many large kindreds show an autosomal dominant pattern of inheritance, and first-degree relatives of ET patients are approximately 5 times more likely to develop the disease than are members of the population and 10 times more likely if the proband's tremor began at an early age. The prevalence of a family history of ET is high in ET patients seen in neurologic clinics and even higher in younger onset than older onset ET cases. A variant in the *LINGO1* gene has been most consistently associated with ET; however, no major causal genes have been identified so far, and this is likely due to phenocopies, incomplete penetrance, bilineal inheritance, or possibly other modes of inheritance. The existence of sporadic cases (ie, cases without apparent family history), variability in age at onset in familial cases, and lack of complete disease concordance in monozygotic twins all argue for nongenetic (ie, environmental) causes as well. A number of environmental toxins are under investigation, including β-carboline alkaloids (eg, harmane, a dietary toxin) and lead. One epidemiologic study indicated a possible protective role of cigarette smoking and another suggested that higher levels of premorbid ethanol consumption raise the risk of developing ET with the presumed mechanism being Purkinje cell toxicity. The identification of modifiable risk factors would have important implications in terms of disease prevention.

PATHOBIOLOGY

The olivary model of ET, first proposed in the early 1970s, posited that a tremor pacemaker in the inferior olivary nucleus was driving the tremor in ET. However, there are major problems with this model, including the absence of direct empirical support, and therefore, there has been trend to move away from this model. In more recent years, mechanistic research on ET has focused more on the cerebellum and the role it seems to

FIGURE 76.1 Spirals drawn by patients with essential tremor who have moderate arm tremor (A) and severe arm tremor (B).

play in the biology of ET. Interest in the cerebellum was initially motivated by neuroimaging studies, which strongly implicate the importance of this brain region in ET, and clinical studies, which frequently note the presence of cerebellar signs in patients with ET. More recently, controlled postmortem studies have revealed an array of degenerative changes in the cerebellar cortex (Fig. 76.2). These changes, which are centered on the Purkinje cell and neighboring neuronal populations, include an increase in the number of torpedoes and related Purkinje cell axonal changes, an increase in number of Purkinje cell dendritic swellings and a truncation of the Purkinje cell dendritic arbor, increased numbers of heterotopic Purkinje cells, changes at the Purkinje cell–climbing fiber synaptic interface, and changes at the Purkinje cell–basket cell interface. In well-designed studies, there is actual Purkinje cell loss and an increase in the numbers of empty basket cell plexuses—a marker of Purkinje cell loss. A smaller group of ET cases demonstrates a pattern of Lewy bodies that are relatively restricted to the locus ceruleus. Of mechanistic interest is that the noradrenergic neurons of the locus ceruleus project to the cerebellum and synapse with Purkinje cells. Hence, there is growing support for the notion that the cerebellum may be central to disease pathobiology and that the pathobiology is neurodegenerative.

CLINICAL MANIFESTATIONS

Introduction

Symptoms and signs of ET can begin at any age, and about 5% begin in childhood, although the incidence increases markedly with advancing age, and most prevalent cases are age 60 years or older.

Tremor

The cardinal feature of ET is kinetic tremor, evidenced during a variety of activities on neurologic examination (eg, finger-nose-finger maneuver, spiral drawing) (▶ Video 76.1). The tremor is generally mildly asymmetric, affecting one arm more than the other, with on average an approximate 30% difference between sides; in approximately 5% of patients, the tremor is markedly asymmetric or even unilateral. In approximately 50% of patients, the tremor has an intentional component, worsening on finger-nose-finger maneuver as the patient approaches one or both of the two targets (▶ Video 76.2). Intention tremor is not limited to the arms; in 10% of patients, it is detectable in the head when the patient's head approaches a target (eg, as head moves down toward target while drinking from a cup or a spoon). Postural tremor also occurs in patients with ET and is generally worse in the wing-beat position than when the arms are held straight in front of the patient. The tremor in the two arms is generally out of phase, sometimes creating a seesaw effect when the arms are held in a wing-beat position and contributing to the observation that functionality may improve when two rather than one hand is used (eg, while holding a cup). The postural tremor of ET is generally greatest in amplitude at the wrist or elbow joints rather than more proximal or distal joints and generally involves wrist flexion extension rather than wrist rotation supination. As a rule, the amplitude of kinetic tremor exceeds that of postural tremor, and the converse pattern should raise questions about the diagnosis. Tremor at rest, without other cardinal features of parkinsonism, occurs in approximately 20% of patients with ET attending a specialty clinic, but in contrast to that of Parkinson disease (PD), it is a late feature, and it has only been observed in the arm rather than the arm and leg.

FIGURE 76.2 **A:** Calbindin-stained section of the cerebellar vermis of an essential tremor (ET) case (×100). Torpedoes (two *arrows*, ovoid swellings of the proximal portion of the Purkinje cell axon) occur in significantly greater numbers in ET cases than controls and are markers of an abnormal Purkinje cell biology. **B:** Calbindin-stained section of the cerebellar cortex of an ET case (×200). From left to right, one can see the Purkinje cell body *(arrow)*, the normal thin initial axonal segment *(long, thin arrow)*, the torpedo *(arrowhead)*, and the thickened axon with recurrent collateral formation *(dotted arrow)* and terminal branching of the Purkinje axon. These morphologic changes occur to a greater degree in ET cases than controls and are markers of an abnormal Purkinje cell biology. **C:** Calbindin-stained section of the cerebellar cortex of an ET case (×200). Hypertrophy of the basket cell processes is seen (two *arrows*, "hairy baskets"); in some instances, there is Purkinje cell loss and the baskets are empty (two *arrowheads*). These changes occur to a greater degree in ET cases than controls and are markers of both an abnormal Purkinje cell biology and reactive changes in the surrounding neuronal populations.

Other Motor Features

Another motor feature of ET, aside from tremor, is gait ataxia, which is in excess of that seen in similarly aged controls. In most patients, this is mild, although in some, it may be of moderate severity. There is some evidence that gait ataxia is more pronounced in patients with midline cranial tremors (eg, neck, jaw, voice). Saccadic eye movement abnormalities have also been detected in ET patients in several physiologic studies, although these are of a subclinical nature.

Nonmotor Features

Recent years have witnessed an increasing appreciation of the presence of nonmotor features in ET patients, which may broadly be classed into cognitive, psychiatric, and sensory. Cognitive changes are in excess of those seen in similarly aged controls and range from mild changes across several domains, but especially executive function, to mild cognitive impairment and dementia, both of which occur to a greater extent than in age-matched controls. Indeed, epidemiologic studies demonstrate that the presence of ET increases the risk of incident dementia by more than 50%. The pathobiology of these cognitive changes is unclear at present but is likely to be multifactorial, involving cerebellar as well as more widespread degenerative pathologies. Psychiatric manifestations include secondary anxiety and depression. The presence of a primary mood disturbance, which precedes the motor manifestations, is supported by at least one prospective study. A harm avoidant personality has been reported in studies that have assessed personality traits in ET, and this may be one feature, which makes patients reluctant to undergo therapeutic surgery even in the setting of severe and disabling tremor. Sensory changes include diminished hearing in excess of that seen in age-matched controls and a mild olfactory deficit in some although not all studies.

Natural History

Initially, the tremor may be mild and asymptomatic and it may not worsen for years, but in most individuals, the tremor worsens over time. Several patterns of progression have been described (Fig. 76.3). The two most common are (1) late life onset and (2) early life onset with mild, stable tremor for many years and then a late life worsening. The least common pattern is that of early life onset with marked worsening over the ensuing years to decade. There are few prospective, longitudinal natural history studies, but the best estimates of rate of change indicate that arm tremor worsens by 2% to 5% per year. With the progression of time, there is a tendency for the spread of tremor beyond the arms, such that patients develop cranial tremors (neck, voice, jaw), particularly in women with ET, among whom the risk of neck tremor is several-fold higher than that of men with ET. The prevalence of neck tremor is the highest of these, with voice tremor being less so and jaw tremor being even less so. Neck tremor is generally of either a "no-no" (ie, horizontal) variety or a "yes-yes" (ie, vertical) tremor and, as the disease progresses, may develop into a more complex tremor with a rotatory component. Unless severe, the neck tremor, which is a postural tremor, should subside and resolve when the patient is recumbent. Isolated neck tremor, with minimal or no accompanying arm tremor, is extremely rare and should raise suspicion that the diagnosis is dystonia rather than ET.

FIGURE 76.3 Three patterns of progression in essential tremor. The two most common are (1) late life onset *(blue dashed line)* and (2) early life onset with mild, stable tremor for many years followed by late life worsening *(purple dotted line)*. The least common pattern is that of (3) early life onset with marked worsening over the ensuing years to decade *(red solid line)*.

A curious feature of the neck tremor is that patients are often unaware of its presence, particularly when it is mild. The presence of dystonic postures in ET cases is controversial, although it is likely that the presence of mild dystonia in some cases does not preclude a diagnosis of ET, especially when the dystonia is a late finding in a case with long-standing and severe ET.

Associated Morbidity and Mortality

Although in the past ET was often viewed as a "benign" problem, the term *benign essential tremor* is no longer considered appropriate. Indeed, the majority of patients have tremor-related disability, and 15% to 25% are sufficiently motorically disabled by high-amplitude shaking that they cannot continue to work. Studies of risk of mortality are limited; the one longitudinal, prospective study that enrolled a controlled group reported an increased risk of mortality in ET of 45%.

The ET patients have about a fourfold increased risk of developing incident PD, thereby developing what is referred to as *essential tremor–Parkinson disease* (ET-PD). The pathobiology of this connection is not fully understood.

DIAGNOSIS

The ET is a clinical diagnosis, made without accompanying laboratory tests because there is no biomarker for ET. Thirty percent to 50% of "ET" cases are misdiagnosed and do not have ET, with many of these cases having dystonia or PD. Differentiation may be made readily, however, by the absence of rigidity or bradykinesia or other signs of parkinsonism (eg, hypomimia) in these cases. The characteristics of the tremor are also important in distinguishing an ET patient from one with PD (Table 76.1). The presence of isolated postural tremor (with minimal kinetic tremor), a postural tremor involving the metacarpophalangeal joints rather than the wrist, and a postural tremor characterized by greater wrist rotation than flexion and extension are all indicators that the likely diagnosis is emerging PD rather than ET (see Table 76.1). Reemergent tremor is a postural tremor that commences after a brief latency, rather than immediately, and is a feature of PD. Dystonia in the arm is characterized by dystonic posturing (eg, "spooning of the fingers" [ie, the tendency during arm extension to flex the wrist and hyperextend the metacarpophalangeal and phalangeal joints]) and the presence of a tremor that is neither rhythmic nor oscillatory. The possibility of neck dystonia should be assessed and is characterized by head tilt or rotation with head tremor, hypertrophy of the sternocleidomastoid muscle, the presence of a tremor null point, and a sensory trick by history (Table 76.2). Absence of cerebellar speech (ie, either scanning or dysarthric) and nystagmus distinguishes ET from the spinocerebellar ataxias. Hyperthyroidism or the use of medications such as lithium or valproate is usually excluded by clinical history. A difficult differential is between a mild case of ET and enhanced physiologic tremor, although the presence of neck tremor should exclude the latter. Computerized tremor analysis, with inertial loading, can assist with this differential. In patients with a tremor of central origin (ET), the primary tremor frequency should not change with inertial loading.

TABLE 76.1 Clinical Examination Features That Help Distinguish Essential Tremor From Parkinson Disease

	ET	PD
Rest tremor (arms)	+[a]	+
Rest tremor (legs)	−[a]	+
Kinetic tremor (arms)	+	+[b]
Postural tremor (arms)	+	+[c]
Intention tremor (arms)	Common	Rare
Reemergent tremor	−	+
Head tremor	Common	Rare
Jaw tremor	+[d]	+
Voice tremor	+	−
Rigidity	−[e]	+
Bradykinesia	−[f]	+
Hypomimia	−	+
Tachyphemia	−	+

Abbreviations: +, present; −, absent; ET, essential tremor; PD, Parkinson disease.
[a]When present, rest tremor generally occurs in ET cases with disease of longer duration and greater severity rather than mild cases of short duration. It is restricted to the arms.
[b]The kinetic tremor of ET is generally of higher amplitude than that of PD, although this is not always the case.
[c]A postural tremor involving the metacarpophalangeal joints rather than the wrist or elbow and a postural tremor characterized by greater wrist rotation than flexion and extension are both indicators that the likely diagnosis is emerging PD rather than ET. An isolated postural tremor (with minimal or no kinetic tremor) is a feature of PD rather than ET. The presence of flexed posturing of the fingers during arm extension is often a sign of PD.
[d]The jaw tremor in ET generally occurs when the mouth is open (eg, while talking or while saying "ahhhhh"); in PD, it generally occurs while the mouth is closed.
[e]During passive movement, the movement may be ratchety, with cogwheeling, but there should be no rigidity.
[f]Older ET patients may have ratings of 1 on the motor portion of the Unified Parkinson's Disease Rating Scale.

TREATMENT

The tremor may be severe enough to result in embarrassment and functional disability, and these are the main motivations for treatment. β-Blockers (especially propranolol) LEVEL 2[1] and

TABLE 76.2 Clinical Examination Features That Help Distinguish Essential Tremor From Dystonia

	ET	Dystonia
Rhythmic and oscillatory tremor	+	+/−
Tremor has a directional quality.	−[a]	+
Tremor null point	−[b]	+
Head tremor resolves while supine.	+	−
Head tremor with little or no arm tremor	Rare[c]	+
Head tilt or rotation	−	+
Hypertrophy of the sternocleidomastoid or other neck muscles	−	+
Voice breaks with voice tremor.	−	+/−
Dystonic posturing in hands (eg, "spooning")	−	+

Abbreviations: +, can be present; −, absent; ET, essential tremor.
[a]Dystonic tremor often has a directional quality seeming to move in one direction more than the opposite.
[b]Tremors, in general, are very positionally dependent in ET, but this should not be confused with a null point.
[c]Isolated head tremor should be a clue that the diagnosis is likely to be dystonia rather than ET.

primidone LEVEL 1,[2] alone or in combination, are the most effective pharmacologic therapies, although many patients chose to discontinue these medications due to their limited efficacy. Propranolol has been used in doses up to 360 mg daily, although doses in excess of 100 mg are rarely tolerated in the elderly due to bradycardia. Asthma is a relative contraindication to the use of propranolol but is not an absolute contraindication and must be assessed on a case-by-case basis; in general, more severe and more recent history of asthma are of greater concern. Primidone is given in doses up to 1,500 mg daily, although lower doses are often effective. An acute nausea and/or ataxia is observed in approximately 25% of patients who are prescribed this medication, and preloading the patient with phenobarbital (eg, 30 mg twice a day for 3 days) is one method that is used to avoid this unwanted side effect. Somnolence and cognitive effects may further limit the use of primidone in older patients. These drugs reduce the amplitude of tremor in 30% to 70% of patients, but they do not abolish it unless the tremor is mild. Other agents that have been used include topiramate LEVEL 1,[3] gabapentin LEVEL 1,[4] and benzodiazepines (alprazolam or clonazepam) LEVEL 1.[5] Many patients note that tremor is temporarily suppressed by drinking ethanol, but a rebound exacerbation sometimes follows the next day. Botulinum toxin injections have been shown to be effective in the treatment of wrist and other upper limb tremors in ET, although muscle weakness may occur LEVEL 1.[6] Weighted utensils and utensils with sensors that use activation cancellation of tremor technology may also provide limited benefit in some patients. High-frequency thalamic stimulation markedly reduces the severity of the tremor and has replaced stereotactic thalamotomy as the treatment of choice for severe pharmacologically refractory tremor. Several other emerging surgical therapies are currently under evaluation, particularly magnetic resonance imaging–guided focused ultrasound thalamotomy.

OUTCOME

As noted in detail earlier, ET is in general a progressive disorder (see Fig. 76.3), with a gradual worsening and spread of tremor over time. At this time, there are no medications that slow or halt this progression.

Tics and Tourette Syndrome 77

Harvey S. Singer

KEY POINTS

1. Tourette syndrome is a complex heterogeneous disorder consisting of variable chronic motor and vocal (phonic) tics and coexisting neuropsychological problems.
2. Tics typically appear in the first decade of life and, in many, diminish in the teenage to early adulthood years.
3. About 85% of Tourette syndrome patients have at least one coexisting neuropsychological condition—the most common being attention deficit hyperactivity disorder, obsessive-compulsive disorder, anxiety, depression, disruptive behaviors, and academic issues.
4. Although the precise etiology for Tourette syndrome is unknown, there is increasing evidence for it being a polygenic combination of several different genes plus environmental factors.
5. Pathophysiologic models of Tourette syndrome suggest involvement of different components of cortico-basal ganglia-thalamo-cortical circuits and their neurotransmitters.
6. An effective therapeutic plan involves the careful assessment of both tics and comorbidities, providing education, and the stepwise use of behavioral therapy, first tier (α-adrenergic agonist, topiramate) and second tier (typical and atypical antipsychotics, vesicular monoamine transporter 2 inhibitors).

INTRODUCTION

Tourette syndrome, officially listed in *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5), as Tourette disorder, is named after the French physician Georges Gilles de la Tourette, who in 1885 described nine patients with chronic involuntary motor and vocal tics. Historically, there are earlier reports including a case report by Jean Itard in 1825. Tourette syndrome is a highly heterogeneous disorder characterized by the presence of variable motor and vocal tics and a variety of co-occurring problems including attention deficit hyperactivity disorder (ADHD), obsessive-compulsive disorder (OCD), anxiety, mood disorder, and other issues. Estimated to have a prevalence around 1%, this syndrome can have a significant negative impact on quality of life. The etiology is complex and currently believed to be polygenic, involving a variety of genes, with contributing environmental factors. The pathophysiology remains undetermined with ongoing controversies involving neuronal circuitry and specific neurotransmitters. There is no cure for Tourette syndrome, and treatment includes education, behavioral and pharmacotherapy, and neuromodulation.

EPIDEMIOLOGY

The prevalence (number of cases in population at a given time) of tics, especially simple tics in childhood ranges from 4% to 24%. Data on chronic tic disorders, those present for greater than 1 year, has varied enormously (0.25%-5.7%), in part due to wide differences in study methodologies. Studies based on the clinical diagnosis of Tourette syndrome range from 0.3% to 0.76% with those evaluating the general population reporting rates around 1%. A meta-analysis of 13 studies identified a prevalence 0.77%, but when solely boys were assessed, the prevalence rose to 1.06%. Another estimate includes an additional 10 to 30 per 1,000 children and adolescents with a mild, unidentified form. Tic phenomenology and severity appear to be similar between children and adults. Adult-onset tic disorders, however, are often associated with potential environmental triggers, severe symptoms, greater social morbidity, and a poorer response to medications. Tourette syndrome is common in children with autism, Asperger syndrome, fragile X syndrome, and other autistic spectrum disorders, but its presence appears to be unrelated to the severity of autistic symptoms. In one study, 22.8% of Tourette syndrome patients met autistic spectrum disorder criteria using a repetitive and restricted behavioral subscale rather than indicators of social communication.

Mortality rates are reportedly higher in Tourette syndrome and chronic motor or vocal tic disorder, irrespective of the presence of comorbidities. Parents of children with chronic tic disorders have higher rates of psychiatric illnesses, greater in mothers than fathers, although whether this is associated with parental stress or environmental, genetic, or other factors is unclear.

PATHOBIOLOGY

Neurobiology

Motor Circuits

Cortico-basal ganglia-thalamo-cortical (CBGTC) pathways have a major role in the generation of tics, however, which component contains the primary pathophysiologic abnormality is an area of ongoing controversy. Proponents have generally focused on the cortex and basal ganglia, although others have noted the essential integrating activity of the thalamus, the motivational and reward aspects of the ventral striatum, or the underrecognized influence of the cerebellum. Lastly, there are those investigators who have suggested that a disruption in multiple sites within the CBGTC circuit, or alterations in brain regions inputting to the circuit, could produce an aberrant message arriving at the primary motor cortex and enabling the tic. Several recent reviews provide an extensive discussion of available clinical and animal model investigative data.

The most frequently presented and simplistic model of motor behavioral control suggests the basal ganglia controls cortical excitability through an interplay of direct and indirect pathways. Three cortical regions (associative/cognitive, motor, and limbic) innervate the striatum with excitatory glutamatergic input: The associative/cognitive pathway arises in dorsolateral prefrontal and parietal regions and projects to the caudate, the motor pathway projects from motor/supplementary motor cortical areas to the putamen, and the limbic (emotional) pathway projects from orbital and medial prefrontal regions to the ventral striatum. Direct and indirect pathways originate from medium spiny neurons (MSNs) within the striatum. The direct pathway transmits striatal information monosynaptically from dopamine D_1 receptor containing MSNs to the globus pallidus interna/substantia nigra pars reticulata (GPi/SNpr), whereas the indirect system conveys information from D_2 receptor containing MSNs to these same regions via a disynaptic relay from globus pallidus externa to the subthalamic nucleus and then to the GPi/SNpr. Each pathway has an opposing effect on GABAergic GPi /SNpr output neurons; the direct pathway GABAergic MSNs inhibit and the indirect pathway, via glutamatergic input from the subthalamic nucleus, stimulates. Functionally, these pathways have a reverse effect on thalamocortical neurons and, in turn, the facilitation/inhibition of motor activity, that is, activation of the direct pathway facilitates motor activity via disinhibition of thalamocortical neurons, whereas activation of the indirect pathway reduces motor activity by increasing the inhibition of thalamocortical neurons. Although many investigators focus on this "two pathway model," it is essential to recognize that the CBGTC circuit is very complex with extensive interactions among its various components.

Neurotransmitters

Neurochemical hypotheses regarding dysfunctional synaptic mechanisms in tic pathology have implicated virtually all neurotransmitter systems located in CBGTC circuits (ie, dopamine, glutamate, γ-aminobutyric acid, serotonin, acetylcholine, histamine, norepinephrine, adenosine, endogenous cannabinoids, and opioids). Unfortunately, like other aspects involving the pathophysiology of tics, the final answer remains unknown. In general, published evidence associating a neurotransmitter with tics has included clinical responses to specific classes of medications, quantitative measurements, imaging protocols, genetic protocols, postmortem brain tissue analyses, and data from animal studies. Several published reviews extensively discuss the evidence supporting individual neurotransmitter abnormalities in Tourette syndrome.

Available neurochemical evidence in Tourette syndrome supports a role for dopamine, including presynaptic and postsynaptic dysfunctions and a preferred intrasynaptic abnormality involving the phasic (stimulus-induced) release. Nevertheless, human and animal studies have identified imbalances in other neurotransmitter systems. For example, glutamate (excitatory) and γ-aminobutyric acid (inhibitory) are major transmitters in CGBTC pathways and disruption of their balance in either the cortex or striatum of animal models has induced tic-like behaviors. Furthermore, it is essential to recognize that within complex integrated motor circuits, a change in one neurotransmitter has a significant effect on the function of other interconnected transmitters. Hence, a successful response to a dopamine antagonist does not necessarily indicate that dopamine is the primary neurotransmitter.

Genetics

Both twin and family studies support a genetic, non-mendelian, etiology for Tourette syndrome. Data includes (1) a positive family history for tics in about one-half of patients, (2) a greater concordance rate with chronic tic disorder in monozygotic twins (86%) compared to dizygotic twins (20%), and (3) a population-based heritability estimate of 0.77—a value of 1 indicating 100% heritability. Nevertheless, despite the support for heritability, numerous studies of multigenerational families have failed to identify a definitive major effect gene. In contrast, current reports suggest a polygenic disorder, that is, one due to a variety of genes (common, rare, low and high effect) plus environmental factors. Several susceptibility (risk) genes have emerged but are not fully confirmed. These include the *SLITRK1* gene, located at 13q31.1, and a mutation in the gene encoding L-histidine decarboxylase. Studies searching for copy number variations (microdeletions or duplications) have identified a few significant changes conferring increased risk including deletions in *NRXN1* (encodes neurexin 1) and duplications of *CNTN6* (encodes contactin 6). Genome-wide association studies have not identified a single significant marker, and the top Tourette syndrome–associated single nucleotide protein was on chromosome 12q22 32kb distal to netrin-4; hence, another possible Tourette syndrome susceptibility gene. Lastly, in expanded whole exome sequencing studies, individuals with unaffected parents had several de novo variants including genes for cadherin and those relating to cell polarity. Clearly, further studies are required to clarify the link between susceptibility genes, clinical findings, and pathophysiology. Investigations pursuing a shared genetic link between Tourette syndrome and OCD have not identified shared gene variants but have shown a significant overlap of de novo sequence variants. Polygenic heritability in Tourette syndrome is shared with OCD, ADHD, and migraine.

Immune System

Autoimmune factors are suggested as both primary and contributing influences for tics. Initially described more than two decades ago, pediatric autoimmune neuropsychiatric disorder associated with a streptococcal infection (PANDAS) is an extremely controversial disorder. Symptoms include the acute, dramatic, explosive onset of a tic and OCD and the presence of infection-related group-A β-hemolytic streptococcal exacerbations. Its proposed pathophysiologic mechanism is the presence of streptococcal-induced polyreactive antibodies, which, through the process of molecular mimicry, recognize and disrupt either neuronal extracellular surface or intracellular antigens. Numerous studies, however, have raised significant concerns about the existence of this entity based on both its clinical criteria and proposed presence of antineuronal antibodies.

A microglial (glial cells belonging to the monocyte/macrophage lineage) hypothesis suggests that various factors (environmental, psychological, infectious, genetic) can "prime" these cells, which in turn alter synaptic formation and elimination. Supporting data includes a postmortem study showing upregulation of inflammatory response transcripts, a positron emission tomography study demonstrating increased binding to the translocator protein receptor present in activated microglia, and an RNA sequencing study of postmortem striatum identifying upregulated genes involved with microglial activation. Some patients with Tourette syndrome also have a variety of isolated immune findings including abnormal

T regulatory cells, elevated cytokines, an impaired innate immune response to bacterial infections, elevated adhesion molecules, and intrathecal oligoclonal bands.

CLINICAL MANIFESTATIONS

Tics, both motor and vocal (also called *phonic*), are sudden, rapid, brief, recurrent, nonrhythmic movements or vocalizations that have a limitless repertoire and variable amplitude and frequency. They often occur repetitively within a short inter-tic interval and are separable into simple and complex categories (Table 77.1). Although often considered a hallmark of Tourette syndrome, coprolalia occurs in only approximately 10% of cases.

The frequency and intensity of tics varies greatly. In some individuals, tics are barely noticeable, whereas in others, they can be very frequent, forceful, intrusive, and even self-injurious. Stress, anxiety, fatigue, elevated temperatures, and infections exacerbate tics. In some, tics are induced by seeing or hearing other people's actions/words or worsened by discussions about their tics. These changes, however, do not usually account for the more prolonged fluctuations and variability of tics. Tics tend to be reduced when individuals are involved in activities that require concentrating and being focused, such as when given tasks to perform during their physical examination, playing the piano, or participating in sports. Although, the typical history includes the absence of tics during sleep, formal polysomnograms have documented their presence during various sleep cycle stages.

The majority (about 90%) of older children and adults describe an uncomfortable sensation that occurs just before the tic (premonitory sensation) and many report an "urge" to tic. Expressed as a feeling of tightness, tingling, tension, pressure, itchiness, distress or "difficult to define," the premonitory sense is often localized to the region of the tic and resolves when the motor/vocal tic is performed. Some report a brief feeling of relief after the tic has occurred. Others are able to briefly suppress their tics for a limited period of time—often at the expense of a mounting discomfort. Neurologic examination and neuroradiographic studies are typically normal. "Soft" signs, including abnormalities of coordination and fine motor performance, synkinesis, and motor restlessness, are frequently present in affected children especially those with ADHD.

TABLE 77.1 Motor and Vocal Tics

Simple motor tics	Simple motor tics include eye blinking, nose twitching, facial grimaces, head jerks, and shoulder shrugs, etc.
Complex motor tics	More elaborate movements that include: 1. A combination of simple movements in a fixed pattern 2. Coordinated actions such as touching, jumping, bending, and gyrating 3. A prolonged "tonic" action (sustained posturing, ocular deviation, torticollis) that can last for a few seconds to minutes 4. Obscene gestures (copropraxia) 5. Imitation of observed movements (echopraxia)
Simple vocal tics	Sudden sounds or noises (throat clearing, sniffs, grunts, barks, hoots, hollers, moans, groans, and other animal sounds)
Complex vocal tics	More meaningful utterances that include: 1. Repetition of syllables, words, or phrases 2. Echolalia (repeating other people's words) 3. Palilalia (repeating one's own words) 4. Coprolalia (the utterance of obscene words)

DIAGNOSIS

DSM-5 Tic Disorder Diagnoses

A tic disorder diagnosis is based on the history and observation of the movement or vocalization. There is no confirmatory laboratory test. The DSM-5 includes five categories: provisional tic disorder, chronic (motor or vocal) tic disorder, Tourette disorder, other specified tic disorder, and unspecified tic disorder (Table 77.2).

Adult-onset tic disorders do occur and often include more severe symptoms, greater social difficulties, and a poorer response to medications. Tics occur in association with a variety of sporadic, genetic, and neurodegenerative disorders including neuroacanthocytosis, Huntington disease, Hallervorden-Spatz syndrome, neurocutaneous syndromes, and Creutzfeldt-Jakob disease. Tics have also been reported in association with infections (encephalitis, Sydenham chorea), drugs, toxins (carbon monoxide), stroke, head trauma, peripheral trauma, and surgery. Drugs reported to induce tics include cocaine, lamotrigine, and neuroleptics. Proof for a substance-induced tic disorder requires that the tics developed either during or within 1 month of substance intoxication or withdrawal. There is little scientific evidence to support the belief that stimulant medications are a precipitating agent for tics.

TABLE 77.2 Tic Disorder Diagnoses

Provisional tic disorder	Indicates an individual whose tics (motor and/or vocal) have been present for less than 1 year since first tic onset and onset is before age 18 years. The disturbance cannot be attributable to the psychological effects of a substance or other medical conditions.
Chronic motor or vocal tic disorder	Indicates the presence of either motor or vocal tics, but not both, for a duration of greater than 1 year, without regard to tic frequency. Onset must be before the age of 18 years and not be attributed to the use of drugs or other medical conditions.
Tourette disorder (also commonly called Tourette syndrome)	Requires an onset before age 18 years, the presence of multiple motor and at least one vocal tic, a waxing and waning course, a duration of longer than 1 year, and that tics are neither substance-induced nor due to a general medical condition
Other specified tic disorder	This diagnosis is appropriate when the patient has tics but fails to fulfill criteria for any of the above tics disorders. In the "other specified tic disorder" category, the reason why the individual failed to meet the aforementioned criteria must be provided, for example, other specific tic disorder "due to an age of onset older than 18 years" or "due to the presence of substance-induced disorder."
Unspecified tic disorder	This diagnosis is appropriate when the patient has tics but fails to fulfill criteria for any of the above tics disorders. In the "Unspecified tic disorder" category, the reason why the individual failed to meet the aforementioned criteria is not provided.

Scales

A variety of clinical rating scales can be used to monitor tic severity. The Yale Global Tic Severity Scale, a semistructured clinical interview, is the most widely used tic assessment instrument. It was recently revised based on its psychometric properties. The scale ranks motor and vocal tics based on their number, frequency, intensity, complexity, and interference. A separate Tic Impairment Score ranks impairment based on the impact of tics on self-esteem, family life, and social acceptance. Other rating scales include the Motor tic, Obsessions and compulsions, Vocal tic Evaluation Survey and the Modified Rush Video-based Rating Scale. The Premonitory Urge for Tics Scale characterizes and quantifies premonitory urges on a global scale, whereas the Individualized Premonitory Urge for Tics Scale provides complementary information on the presence, frequency, and intensity of urges for individual tics. Recognizing that tic severity does not necessarily correlate with overall quality of life, the Gilles de la Tourette syndrome Health-Related Quality of Life Scale, with psychological, physical, obsessional, and cognitive subscales, can provide an important assessment.

Coexisting Conditions

Although the diagnosis of Tourette syndrome only requires the presence of tics, approximately 85% of patients with this disorder have coexisting neuropsychological conditions, that is, only 10% have "pure" Tourette syndrome. For many individuals, these additional issues have a greater negative clinical impact than those directly caused by tics. Several, such as ADHD and OCD, appear genetically linked to Tourette syndrome, although the relationship is complex. Other frequent co-occurring conditions, with a less likely genetic association, include anxiety and depressive disorders, disruptive behaviors, conduct problems, suicidality, sleep disturbances, self-injurious behaviors, academic difficulties, and migraine headaches. A recent study has also suggested that cardiovascular problems and obesity are common in Tourette syndrome patients, unrelated to the use of antipsychotic medications.

Attention Deficit Hyperactivity Disorder

The ADHD, defined by the presence of impulsivity, hyperactivity, and a decreased ability to maintain attention to an impairing degree, occurs in about 60% of referred Tourette syndrome patients (range 21%-90%). Symptoms usually begin at age 4 to 5 years and typically precede the onset of tics. The presence of ADHD, not tics, typically correlates with increased psychosocial difficulties, disruptive behavior, emotional problems, functional impairment, learning disabilities, and school problems.

Obsessive-Compulsive Behaviors and Obsessive-Compulsive Disorder

Obsessive-compulsive behaviors are common in individuals with Tourette syndrome (about 60%-90%) with about 40% to 60% having the diagnosis of OCD—the later requiring behaviors to be present for more than 1 hour a day, result in marked distress, or to have a significant impact on normal function or relations. Symptoms usually emerge several years after the onset of tics. Obsessive-compulsive symptoms vary in patients with and without tics. Those associated with tics have a need for order, a requirement for symmetry, frequent checking for errors, hoarding, touching, tapping, rubbing, and a higher frequency of aggressive, sexual, religious, and symmetry-related obsessions. In contrast, symptoms occurring in individuals without tics include cleaning rituals, compulsive washing, and fears of contamination. Clinically differentiating obsessive-compulsive behaviors from complex tics may be difficult. Clues that favor obsessive compulsive symptoms include a cognitive-based drive ("unless I do this, something will happen"), need to perform the action in a particular fashion (ie, a specific number of times, until it feels "just right," or equally on both sides of the body), and the absence of a premonitory urge.

Anxiety and Depression

Anxiety and depression have an increased prevalence in patients with Tourette syndrome; depression affecting from 13% to 76% and anxiety from 19% to 80% depending on the study. In contrast to earlier reports, the age of onset for these symptoms is earlier than originally believed with high-risk periods for anxiety and mood disorders beginning at ages 4 and 7 years, respectively. The etiology of these symptoms appears to be multifactorial but not genetic. Anxiety and disruptive behaviors are partially mediated by ADHD, whereas mood disorders are influenced by comorbid OCD.

Other Psychopathologies

Disruptive antisocial and oppositional behaviors, aggression, personality disorder, problems with anger control, nonobscene socially inappropriate behaviors, and schizotypal traits are more frequent in Tourette syndrome. Self-injurious behaviors occur in a minority of patients. Like anxiety and depression, these behavioral and emotional problems are associated with obsessionality, ADHD, and impulsivity, rather than just the presence of tics. Suicidality, both thoughts and attempts, have a higher incidence in Tourette syndrome. Children with Tourette syndrome are also more likely to have sensory hypersensitivity.

Academic Issues

Individuals with Tourette syndrome typically have normal intellectual functioning, although learning problems may coexist in about 30% to 40%. Documented issues have included concurrent executive dysfunction, impaired visual-motor and visual-perceptual skills, and discrepancies between performance and IQ testing. Poor academic performance may also be secondary to severe tics, psychosocial issues and bullying, ADHD, OCD, learning difficulties, sleep problems, or side effects from prescribed medications.

Sleep Disorders

A wide range of sleep difficulties, including difficulties falling asleep, staying asleep, restless sleep, frequent arousals, and parasomnias, are common in Tourette syndrome. Whether all of these problems are primarily due to coexisting problems is unclear. The effective management of sleep problems has improved the severity of tics and quality of life.

MANAGEMENT

Initial Management

The initial step in establishing a treatment plan for Tourette syndrome (Fig. 77.1) includes (1) the evaluation of tics, their severity, and resulting impairment; (2) determining the presence of coexisting conditions and their impact on daily functioning

FIGURE 77.1 Management of tics. Abbreviations: CBIT, comprehensive behavioral intervention for tics; DBS, deep brain stimulation; ERP, exposure response prevention; HRT, habit reversal training; rTMS, repetitive transcranial magnetic stimulation; VMAT2, vesicular monoamine transporter 2.

and quality of life; and (3) in conjunction with the patient, family, and school/work personnel, determining which symptoms are the most prominent and disabling. An early discussion of tics and comorbid symptoms as separate entities enables families and health care specialists to focus on the patient's immediate needs more effectively. For example, in many instances, ADHD, OCD, anxiety, disruptive behaviors, or mood symptoms may cause more immediate problems than tics. Furthermore, providing clear and accurate information and allowing adequate time for questions and answers enhances the ability of patients and families to understand the numerous issues surrounding this complex and heterogeneous disorder. Lastly, all need to recognize that there is no cure for tics, only symptomatic therapy.

Therapy is reserved for functionally disabling tics. The treatment of a child with Tourette syndrome often requires a comprehensive multidisciplinary approach, especially in those individuals with academic or psychiatric difficulties. Regarding tics, for many, educational insight about their diagnosis, outcome, coexisting problems, etiology, neurobiology, and indications for therapy often obviates or delays the need for treatment. Tics fluctuate, and supportive care is often adequate for individuals with milder tics. Specific criteria for initiating tic-suppressing therapy includes either (1) the presence of psychosocial problems (eg, loss of self-esteem; peer problems; difficulty participating in academic, work, family, social, and after-school activities), (2) tic-induced musculoskeletal/physical difficulties (eg, neck discomfort associated with frequent head jerks), (3) and the disruption of classroom/work settings (eg, sounds, noises, or movements that interfere with a classmate's ability to concentrate on the lesion). If tics warrant treatment, behavioral interventions are first-line therapy. The goal of treatment is to reduce tics to a degree at which they are no longer causing significant problems.

Behavioral Treatment for Tics

Behavioral interventions include habit reversal training (HRT), comprehensive behavioral intervention for tics (CBIT), and exposure response prevention (ERP). The neurobehavioral model acknowledges the neurobiologic nature of tics but suggests tics are influenced by internal (premonitory urges) and external (stress, environmental) factors. The behavioral strategies taught in treatment are aimed at interrupting (and ultimately discontinuing) the reinforcement of tics by these internal and external factors. Despite the efficacy of behavior therapy for Tourette syndrome, a limited number of providers are trained to deliver this treatment, which poses a barrier to its use in the community.

Habit Reversal Training

While HRT can consist of several components, there are three components that are considered central to treatment: awareness training (recognizing the urge or tic occurrence), competing response training (performing a socially discrete behavior that is physically incompatible with the tic and can be maintained for up to 1 min, eg, for an arm jerking tics, a competing response might be folding arms across the chest for up to 1 min or until the urge resolves), and social support (a home-based provider to deliver developmentally appropriate praise for correct implementation). Individual tics are addressed at a rate of one per week.

Comprehensive Behavioral Intervention for Tics

The CBIT is an extension of HRT. Whereas HRT primarily focuses on internal factors, CBIT incorporates additional skills to address external factors that influence the expression of tics. Specifically, CBIT incorporates the three core components of HRT and also includes relaxation training to manage anxiety and stress and functional-based interventions to address external factors that influence tic expression. The CBIT also provides patients and families psychoeducational training about Tourette syndrome and a reward procedure to enhance compliance (when needed). A typical program includes weekly sessions over a 10-week period but may vary depending on the number of tics. Several studies have confirmed the efficacy of CBIT to reduce tics in children and adults, both short-term and in 6-month follow-up studies, without adverse effects LEVEL 1.[1,2] Treatment is beneficial for patients with tics plus ADHD/OCD, and individuals not receiving tic-suppressing medications did better than those on medication. The precise biologic mechanism underlying tic improvement is unknown but may involve habituation to the premonitory urge or inhibition of the tic. The CBIT is the recommended behavioral approach—it is effectively delivered in person, via teleconferencing, and Internet.

Exposure Response Prevention

The ERP is another promising behavioral intervention that shares some similarities to HRT. Whereas HRT targets individual tics using compensatory behavioral responses, ERP seeks to target all tics simultaneously by capitalizing on a patient's inherent ability to suppress tics. Over time, patients habituate and/or develop a tolerance for the premonitory urge. Treatment begins with patients practicing simultaneously suppressing all tics, and the duration of this practice increases over subsequent sessions. As the patient develops initial mastery over tic suppression, greater exposures are completed to increase the difficulty of therapeutic exercises (ie, focusing on premonitory urges, talking about tics, focusing on the part of the body experiencing the urge, exposure to situations that exacerbate tics) that strengthens tic suppression abilities.

Complementary and Alternative Medications

The use of complementary and alternative medications (CAMs) in Tourette syndrome is widespread. In a clinic-based survey of Tourette syndrome patients, 64% reported using at least one CAM, and 29% used more than three agents. The list of CAMs is extensive and includes nutritional supplements (vitamins B, C, and E; magnesium; calcium; fish oil; flaxseed oil; omega-3 fatty acids) and herbal medicines (Ningdong Granule, 5-Ling Granule, qufeng zhidong recipe, clerodendrum inerme plant). Few randomized controlled trials have been reported, and the majority contain only a small study population. Ningdong Granule and the 5-Ling Granule were more effective than placebo. Acupuncture, self-hypnosis, music therapy, biofeedback, and plum-blossom needle therapy have limited scientific support. Physicians should be aware of CAM because patients/families independently implement these treatments.

Pharmacotherapy

Pharmacotherapy should be prescribed, if the patient meets criteria for initiating tic therapy (see earlier discussion) and has either failed behavioral therapy or none is available. Most medications are off-label, with only three (pimozide, haloperidol, and aripiprazole) being U.S. Food and Drug Administration approved. Recent reviews have integrated the current understanding of Tourette syndrome pathophysiology with pharmacotherapy and evaluated the extent of supporting evidence for each medication. The selection of pharmacologic therapy is generally based on personal experience despite the availability of published individual and group guidelines. Medications should initially be prescribed at their lowest effective dosage and gradually increased as needed (Table 77.3). Periodic evaluations are essential to assess medication efficacy, side effects, and the requirement for continued therapy. On average, medications reduce tic symptoms by 25% to 70%, and there is no treatment efficacious for all affected individuals. If tics do not respond to a medication and there is no other resulting benefit (eg, ADHD, anxiety, or mood), it should be withdrawn and another medication substituted in its place. In general, there is a two-tiered approach to tic-suppressing pharmacotherapy: tier 1 medications for milder and tier 2 medications for more difficult to control tics. Recognizing that tics often decline during adolescence, if they are under good control for a significant period, a gradual taper of medication during a nonstressful time is appropriate.

Tier 1 Medications

As a category, tier 1 medications are less effective in suppressing tics but have a preferable adverse-effect profile as compared to tier 2 drugs. Medications in this category include clonidine, guanfacine, topiramate, clonazepam, and baclofen. Therapeutically, the two α-adrenergic agonists (clonidine and guanfacine) are superior to placebo and have beneficial effects for both tic suppression and treatment of ADHD LEVEL 1.[3-6] With both medications, tic reduction effect sizes are greater in children who have comorbid ADHD as compared to those without ADHD. A study comparing extended-release guanfacine to placebo did not identify a clinically meaningful effect size LEVEL 1.[5] Common side effects of α-agonists include sedation, hypotension, and bradycardia. Topiramate was superior to placebo in reducing tics LEVEL 1.[7] Clonazepam and baclofen fall within the insufficient evidence category.

Tier 2 Medications

As a category, tier 2 are more effective than tier 1 medications, but are associated with more significant side effects that frequently limit their usefulness. Medications in this category include dopamine receptor antagonists (typical and atypical antipsychotics) and the vesicular monoamine transporter 2 inhibitors. Randomized clinical trials support the tic-suppressing efficacy of typical (pimozide, haloperidol, tiapride) and atypical (aripiprazole, risperidone, ziprasidone) antipsychotics over placebo LEVEL 1.[3,4,8,9] Comparative studies have, however, failed to establish the clear superiority of any single medication. Fluphenazine, a combined D_1 and D_2 receptor inhibitor, was effective in several small studies, and the D_1 receptor antagonist, ecopipam, has been effective in small adult and pediatric trials. Tiapride and sulpiride have been beneficial in European trials but are not available in the United States. Potential long-term side effects in patients receiving either typical or atypical antipsychotics include weight gain, sedation, drowsiness, hyperprolactinemia, tardive dyskinesia, akathisia, and QTc prolongation.

Vesicular monoamine transporter 2 inhibitors exert their effect by blocking the transport of dopamine into presynaptic vesicles, thereby depleting levels at the synaptic terminal. Tetrabenazine has been shown to be beneficial in open-label trials, although concerns exist about its use in individuals with depression and suicidality. Two new vesicular monoamine transporter 2 inhibitors, deutetrabenazine and valbenazine, are currently in clinical trials. Possible benefits may include fewer side effects and less frequent dosing.

TABLE 77.3 Pharmacologic Treatments of Tics and Supporting Evidence

	Mechanism of Action	Starting Dose (mg)	Daily Dosing (mg)	Side Effects	Supporting Evidence: RCT[a]	Supporting Evidence: "Confidence in evidence"[b]	Supporting Evidence: "More likely than placebo to reduce tics"[c]
Tier 1							
α-Adrenergic agonists							
Guanfacine ER (Intuniv)	α_2-Agonist	1	1-4	Sedation, hypotension, dry mouth, bradycardia, irritability, headache, abdominal pain, fatigue, insomnia, dysphoria	3		
Guanfacine (Tenex)							
Clonidine (Catapres)	α_2-Agonist	0.05	0.1-0.4		1	Moderate	Probably
Clonidine (patch)		0.1		Rash			
Anticonvulsants							
Topiramate	GABAA agonist;	25	25-200	Headache, sedation, diarrhea, confusion, paresthesia, weight loss	1	Low	Possibly
Clonazepam	AMPA antagonist	0.25-0.5	0.5-4	Sedation, fatigue, confusion, dizziness, hyperactivity		N/A	N/A
Other							
Baclofen	GABAB agonist	5-10	10-60	Sedation, drowsiness, GI problems, confusion, anxiety, headache	1	Very low	N/A
Tier 2							
Typical neuroleptics							
Pimozide (Orap)	D_2 antagonist, calcium channel blocker	0.5-1.0	0.5-10	DIMD, sedation, orthostatic hypotension; prolonged QTc, hyperprolactinemia, restlessness, anxiety, weight gain, fatigue, somnolence, gynecomastia, neuroleptic malignant syndrome	6	Low	Possibly
Fluphenazine	D_1/D_2 antagonist	0.5-1	5-10				N/A
Haloperidol (Haldol)	D_2 antagonist	0.25-0.5	0.75-10		5	Moderate	Probably
Atypical neuroleptics							
Aripiprazole (Abilify)	Partial D_2-D_4 agonist; partial 5-HT_{1A}/5-HT_{2C} agonist	2	2.0-20	DIMD, increased appetite, sedation, weight gain, dyslipidemia, hyperprolactinemia, insulin resistance, fatigue, somnolence	4	Moderate	Probably
Risperidone (Risperdal)	5-HT_2 antagonist at low dose; D_2 antagonist at high dose	0.25-4.0	1-4.0	Prolonged QTc, orthostatic hypotension	6	Moderate	Probably
Olanzapine	Antagonist: D_1-D_4, 5-HT_{2A}, 5-HT_{2C}, H_1, muscarinic	2.5-5.0	5-10		0	N/A	N/A
Ziprasidone	Antagonist: D_2 and 5-HT_2	5	10-40		1	Low	Possibly
Quetiapine	Antagonist: D_1, D_2, 5-HT_{1A}, 5-HT_2, and H_1	12.5-25	300-400		N/A	N/A	N/A
VMAT2 inhibitor							
Tetrabenazine		12.5	50-150	Sedation, depression, parkinsonism, insomnia, anxiety, hypotension, akathisia, fatigue, irritability	0	N/A	N/A
Deutetrabenazine		6	18-36		0	N/A	N/A

Other Medications

Botulinum Toxin Injections for Tics

Botulinum toxin injections with onabotulinum toxin A are reserved for severe localized tics (violent head thrusts), dystonic motor tics, and vocal tics. Treatment maybe effective for 12 to 16 weeks, and repeat injections are required. Side effects include weakness and hypophonia.

Cannabis-Based Medications

Several small randomized studies and case reports have suggested that cannabinoids may have a beneficial effect on tics, but evidence is limited. Pharmacologic approaches have included smoking marijuana or using extracts from the cannabis plant, including Δ-9-tetrahydrocannabinol, cannabidiol, and nabiximols (combinations of Δ-9-tetrahydrocannabinol and cannabidiol). The most common side effects are sedation, dizziness, headaches, a "high" (euphoria feeling), red eyes, increased appetite, psychosis, depression, and cognitive impairment. Several reviews have emphasized the lack of evidence with regard to the use of cannabinoids and the requirement for additional testing. A second investigative approach, currently under investigation, involves attempts to modulate the brain's existing endocannabinoid system.

Neuromodulation

Noninvasive Neuromodulation

Repetitive transcranial magnetic stimulation is a noninvasive technique that uses brief repetitive intense magnetic fields generated by a coil placed over the scalp to produce an electromagnetic field in the underlying brain region. To date, there is insufficient evidence to evaluate the efficacy of repetitive transcranial magnetic stimulation of the supplementary motor area, left motor, and parietal cortex. A single, double-blind randomized placebo trial showed no significant difference between active and sham treatment. Similarly, a small study using cathodal transcranial direct current stimulation was unsuccessful in two-thirds of patients with severe tics.

Invasive Neuromodulation

Deep brain stimulation is a stereotactic treatment that has significant potential for the treatment of tics and a recommended patient selection criterion has been published. There is no consensus regarding the optimal brain target for tics, larger studies targeting the centromedian parafascicular complex of the thalamus and GPi and others the dorsomedial thalamus, globus pallidus externa, subthalamic nucleus, ventral striatum, and internal capsule. Appropriate patient selection and a multidisciplinary assessment are essential. Although reports describe a beneficial effect, interpretation is confounded by variations in methodologies, differences in complications, variable use of standard outcome measures, and the lack of a control population. Deep brain stimulation for individuals younger than age 18 years should only be considered for urgent cases of tics causing acute bodily harm and after an ethics committee review.

OUTCOME

Tics usually have their onset in the first decade of life, typically between 4 and 8 years of age. They are more common in males in a ratio of about 3 to 4:1. Motor tics usually precede the appearance of vocal tics and often first occur in the face, head, or neck. Tics have a waxing, waning, and evolving course, some resolving, others recurring or being replaced by new tics. Statistically, peak tic severity occurs between 10 and 12 years of age and is followed by a gradual decline in severity. The author's rule of thirds suggests that in the teenage to early adulthood years, approximately one-third have a resolution of tics, one-third are better, and one-third continue to fluctuate. Whether tics fully resolve is a difficult question because many adults who claim to

be tic free actually have persisting tics when carefully observed. Studies in adults have identified a reemergence or exacerbation of a childhood disorder with prominent facial, neck, and trunk tics. Assumptions that one can predict the outcome of tics based on clinical examination or imaging results are controversial.

CONCLUSION

Tourette syndrome is a complex heterogeneous disorder characterized by the presence of variable fluctuating motor and vocal tics plus a variety of co-occurring neuropsychiatric conditions. The disorder remains a challenge for the patient and their family, the treating physician, and researchers attempting to better understand its etiology and underlying pathophysiology. Improved insights into the neurobiology of Tourette syndrome will hopefully lead to the development of new and innovative disease modifying therapies.

Restless Legs Syndrome 78

Brian B. Koo

KEY POINTS

1. The diagnosis of restless legs syndrome (RLS) is clinical and made by determining the presence of an uncomfortable urge to move the legs which occurs at night and with inactivity and which is relieved by movement. It is essential to rule out any one of several RLS mimics which fulfill the above criteria but do not constitute RLS.
2. The pathophysiology of RLS is complex. The RLS is associated with decreased iron in the striatum and low cerebrospinal fluid ferritin. In RLS, the brain's dopaminergic and glutamatergic systems are hyperactive, whereas central nervous system endorphin pathways have decreased activity.
3. The most important step in treating RLS is to outline and consider elimination of factors which result in exacerbation of RLS. These factors include dietary substances (eg, alcohol, simple sugars, caffeine), habitual factors (eg, smoking, blood donation), over-the-counter medications (eg, antihistamines, melatonin), prescribed medications (antipsychotics, antihistamines, antidepressants), and factors which adversely affect sleep (eg, sleep apnea).
4. The $\alpha 2\delta$ ligands, gabapentin and pregabalin, are first line for the treatment of RLS.
5. If dopamine agonists are to be used to treat RLS, the maximum dosages for RLS (ropinirole 4.0 mg; pramipexole 0.75-1.0 mg; rotigotine 4.0 mg) should not be exceeded as higher doses are associated with high levels of augmentation.
6. Augmentation consists of a worsening of RLS in the setting of long-term dopaminergic therapy and consists of RLS symptoms occurring at earlier times in the day, spreading to previously uninvolved body parts, or having increased intensity. Treatment of augmentation consists of eliminating or at least lowering the dose of the offending dopaminergic agent while using another nondopaminergic agent to treat RLS symptoms.

INTRODUCTION

Restless legs syndrome (RLS), also known as *Willis-Ekbom disease*, is a neurologic sensorimotor disease defined by the presence of four essential criteria: (1) an urge to move the limbs occurring with or without uncomfortable sensations, (2) worsening of the symptoms at rest, (3) improvement with activity, and (4) occurrence of symptoms in the evening or night. The RLS severity and frequency vary greatly from individual to individual. In mild cases, RLS symptoms may occur a few times per year and have minimal clinical impact, whereas in severe cases, RLS can occur nightly and have a profound negative impact on sleep and overall well-being. It is important to note that RLS severity and frequency are influenced by a myriad of factors which include other disease states, medications, foods or beverages, and mental state. The RLS is often chronic, and in severe cases, lifelong treatment is needed. Other clinical features typical for RLS include the tendency for symptoms to gradually worsen with age, a positive therapeutic effect of dopaminergic medications, a positive family history, and the co-occurrence of periodic limb movements during sleep (PLMS). Traditionally, the neurologic examination is normal in RLS; however, leg/feet stereotypies are sometimes present later in the day, although usually suppressible.

The RLS may be split into primary and secondary forms. In primary or idiopathic RLS, onset is often in childhood or young adulthood, and there are no associated comorbid disease states, whereas in secondary RLS, RLS occurs in the setting of a disease state which predisposes to RLS, such as end-stage renal disease, Parkinson disease, multiple sclerosis, or pregnancy.

EPIDEMIOLOGY

The epidemiology of RLS has been studied extensively. In general, the prevalence of RLS occurring at any frequency or severity in North America and Western Europe is between 5% and 10%, whereas the prevalence of clinically significant RLS (occurring twice per week with at least moderate distress) is about 2% to 4%. In general, northern European countries have demonstrated the highest prevalence of RLS, followed by Germanic/Anglo-Saxon, and then Mediterranean countries, following a north-south gradient of declining RLS prevalence. The prevalence of RLS in the United States and Canada is similar to that seen in Western Europe. The RLS prevalence is low in Asia and Africa, with prevalence of RLS at any frequency in Asia around 2% to 4%. One study in Tanzania found only 1 person out of 7,654 people interviewed had RLS. Although this has not been adequately studied, anecdotally African Americans only rarely present with RLS. Women have RLS at a rate compared to men of 2:1. This increased prevalence of RLS is thought to be related to childbearing as the prevalence of RLS increases linearly with parity and is equal to that in men for nulliparous women.

PATHOBIOLOGY

A family history of RLS is present in 40% to 60% of those with idiopathic RLS, and RLS is thought to be inherited in an autosomal dominant pattern. Concordance in the expression of RLS in monozygotic twins is about 80%, but severity and age of onset is variable. To date, eight susceptibility loci for familial

RLS have been identified through familial linkage studies, but a responsible gene has not been identified. Genome-wide association studies have identified association between variants in several genes and RLS. The most robust associations showing genome-wide association included variants in broad-complex, tramtrack, and bric a brac domain-containing 9, myeloid ecotropic viral integration site 1, and protein phosphatase receptor type D genes.

Although there has been significant research to clarify the biologic mechanisms underlying RLS, the pathophysiology of RLS remains incomplete. The most robust and durable observations include those of reduced central nervous system (CNS) iron stores, even in the setting of normal systemic iron levels. The RLS patients show reduced cerebrospinal fluid (CSF) ferritin, reduced iron on magnetic resonance imaging, especially in the striatum and red nucleus, reduced iron on CNS ultrasonography in the substantia nigra, and, most importantly, reduced iron and iron-related proteins at autopsy, including reduced H-ferritin staining, iron staining, and increased transferrin stains, but also reduced transferrin receptors. In two separate studies comparing ferritin and transferrin in RLS patients compared to healthy controls without RLS, CSF ferritin was significantly lower and CSF transferrin significantly higher in RLS patients, but there was no difference in either ferritin or transferrin in the serum. These findings suggest that there is iron deficiency and iron handling abnormalities specific to the CNS in persons with RLS.

The dopaminergic system has also been rigorously studied in RLS pathobiologic research. The impetus to study the dopamine system in RLS has mainly been driven by the clinical observations that dopamine-blocking medications worsen RLS and dopamine agonist (DA) medications lessen RLS symptoms. Findings related to studying the dopamine system in RLS have generally suggested a state of relative dopamine excess in the brain of RLS patients, despite the predominant early belief of most in the RLS field of the opposite. The first CSF studies in RLS patients demonstrated normal dopaminergic metabolites in persons with RLS, but later studies by a separate group showed significantly higher CSF levels of dopamine metabolites in RLS patients. Findings resulting from neuroimaging studies have been conflicting and difficult to interpret. Positron emission tomography studies have shown increased binding potential of dopamine D_2 receptors in the striatum of RLS patients, no difference in striatal dopamine D_2 receptor binding potential, and reduced binding potential in putaminal dopamine D_2 receptors. A postmortem study of RLS brain tissue revealed significantly increased tyrosine hydroxylase in the substantia nigra and putamen of RLS patients and significantly decreased putaminal dopamine D_2 receptor density, also consistent with an overly active dopaminergic system.

Opioid pathways are also implicated in RLS pathobiology by a nearly universal treatment response of RLS to opioid medications. A postmortem analysis of brains in a limited number of RLS patients and controls found a reduction in β-endorphin–positive and Met-enkephalin–positive cells. The glutamatergic system is also involved in RLS pathobiology. Magnetic resonance spectroscopy has shown that glutamatergic activity is significantly increased in the thalamus of RLS patients compared to matched control individuals and that this activity correlates highly with arousal from sleep. This hyperactivity in the glutamate system may be modulated by yet another neural system, the adenosinergic system. In an iron-deficient rodent model of RLS, iron deficiency was associated with a downregulation of adenosine A_1 receptors and hypersensitive striatal glutamatergic terminals. Furthermore, in this model, both DAs and the $\alpha_2\delta$ ligand, gabapentin, counteracted excessive glutamate release, all suggesting that changes in the adenosine system may modulate overactivity in the glutamate and dopamine systems.

DIAGNOSIS

The diagnosis of RLS is solely clinical and not at all based on information derived from a polysomnogram. Consensus criteria for RLS diagnosis were established by leading experts at a National Institutes of Health conference in 2003, which laid out four essential criteria for RLS diagnosis that are still used to this day. These criteria include (1) an urge to move the legs, usually accompanied by uncomfortable or unpleasant sensations in the legs; (2) the urge to move or unpleasant sensations begin or worsen during periods of rest or inactivity; (3) the urge to move or unpleasant sensations are partially or totally relieved by movement; and (4) the urge to move or unpleasant sensations are worse in the evening or night. In 2012, the RLS diagnostic criteria were revised in the third edition of the International Classification of Sleep Disorders; in addition to the above four essential RLS criteria, these new criteria outlined that the four essential features not be accounted for by another medical or behavioral condition and that the symptoms cause some amount of distress, sleep disturbance, or impairment in mental, physical, social, or occupational functioning (Table 78.1). Indeed, these revised criteria stress the importance of ruling out common RLS mimics (Table 78.2) and demonstrating negative functional consequences of RLS symptoms.

Although not part of the diagnostic nosology of RLS, the classification of RLS into primary idiopathic RLS and secondary RLS may be helpful (Table 78.3). Primary idiopathic RLS often occurs in the first to third decade of life, runs in the family, and has a female predominance. Secondary RLS is RLS which occurs in the setting of diagnoses known to be associated with RLS, such as iron deficiency anemia, Parkinson disease, multiple sclerosis,

TABLE 78.1 International Classification of Sleep Disorders: Three Diagnostic Criteria for Restless Legs Syndrome

1. An urge to move the legs, usually accompanied by or thought to be caused by uncomfortable and unpleasant sensations in the legs. These symptoms must
   A. Begin or worsen during periods of rest or inactivity such as lying down or sitting;
   B. Be partially or totally relieved by movement, such as walking or stretching, at least as long as the activity continues; and
   C. Occur exclusively or predominantly in the evening or night rather than during the day
2. The above features are not solely accounted for as symptoms of another medical or behavioral condition (eg, leg cramps, positional discomfort, myalgia, venous stasis, leg edema, arthritis, habitual foot tapping).
3. The symptoms of restless legs syndrome cause concern, distress, sleep disturbance, or impairment in mental, physical, social, occupational, educational, behavioral, or other important areas of functioning.

TABLE 78.2 Differential Diagnosis of Restless Legs Syndrome (Mimics)

Condition	How Different From Restless Legs Syndrome
Akathisia	Whole body urge to move, associated with dopamine blockers, not as circadian
Cramp	Chaotic visible/palpable muscle contraction, can be stopped by stretching muscle, little urge to move
Myalgia	Muscle ache, may be worse at night but no true urge to move
Neuropathic pain	Usually superficial, burning, electric, feet most involved
Radiculopathy	Usually asymmetric, more position dependent but no urge to move other than to move from painful position
Body positional discomfort	Cannot get comfortable in any position but not a true urge to move
Moving toes, painful legs	Slow writhing dystonic movement of toes/feet, not suppressible

peripheral neuropathy, end-stage renal disease, and pregnancy. Clinically primary and secondary RLS may be indistinguishable on the basis of symptom description and may respond to similar medications. However, the choice of medical treatment can be tailored depending on if RLS co-occurs with specific disorders, such that an α2δ ligand may be favored in the setting of neuropathy or a dopamine agent may be favored when RLS occurs in a patient with Parkinson disease. The RLS, whether primary or secondary, is a chronic disease which often becomes progressively more severe and frequent. Primary or early-onset RLS is more likely to be familial and appears to progress slowly with age. Late-onset, usually secondary, RLS occurs after the age of 45 years, and its severity seems to be associated more with serum ferritin levels, although progression with age also cannot be ruled out.

It should be noted that although frank iron deficiency anemia can be associated with secondary RLS, in primary idiopathic RLS, there is a deficiency of iron and ferritin in the brain, whereas systemic iron deficiency is often not present.

TABLE 78.3 Primary and Secondary Restless Legs Syndrome (RLS)

	Primary RLS	Secondary RLS
Definition	Idiopathic RLS	RLS occurring with a predisposing condition
Onset	First to third decade	Third to seventh decade
Comorbidity	NA	Pregnancy, end-stage renal disease, Parkinson disease, multiple sclerosis, neuropathy, iron deficiency anemia
Treatment	See Table 78.4.	α2δ Ligand if neuropathy; dopamine drug if Parkinson
Prognosis	Progressive	May depend on severity of comorbidity (not necessarily for multiple sclerosis or Parkinson disease)

Abbreviation: NA, not applicable.

MANAGEMENT

Figure 78.1 serves as a flow diagram and an approach to treating RLS. The severity and frequency of RLS symptoms are influenced by numerous dietary, pharmacologic, lifestyle, and biologic factors. Thus, the first step in the management of RLS is to determine if such factors are present. Dietary factors which worsen RLS include alcohol, caffeine, and high amounts of refined, simple sugars. Lifestyle factors which worsen RLS include smoking and too much or too little exercise. Medications which aggravate RLS are first-generation antihistamines (eg, diphenhydramine or any sleeping medicine containing diphenhydramine); dopamine-blocking agents, including antipsychotic and antinausea medications; and antidepressant medications. Whereas any antidepressant which blocks reuptake of serotonin can worsen RLS, those medicines with prominent antihistaminergic activity are most likely to cause RLS worsening, including doxepin, mirtazapine, and amitriptyline. Unfortunately, these medicines are often prescribed in RLS patients with the thought that they will improve sleep. Antidepressant medications which are thought not to cause RLS worsening are bupropion and desipramine. Any factor which interrupts sleep or prevents sleep will also worsen RLS. Insufficient sleep, environmental factors which disturb sleep, and obstructive sleep apnea can all provoke RLS symptoms in a vulnerable individual. The threshold to perform polysomnography to rule out sleep apnea should be low, as the treatment of sleep apnea in particular is important in treating RLS as many times the prescription of medication for RLS can be avoided by treating sleep apnea when comorbid with RLS. Low iron or ferritin levels can also precipitate or worsen RLS.

There are several different medical treatment options for RLS. The development of validated rating scales (International Restless Legs Syndrome Study Group Severity Scale) and standardized diagnostic criteria have vastly improved the quality of RLS treatment trials. Multiple medications have demonstrated efficacy in well-designed class 1 trials, especially the dopaminergics, α2δ ligands, opioids, and iron (Table 78.4). With the possible exception of iron, all are felt to provide only symptomatic relief rather than any curative effect. Therefore, treatment should only be initiated when the benefits are felt to justify any potential side effects and costs. Over time, both dosing and drug changes may be required to maximize benefit and minimize the risk of side effects.

The DAs are the most widely investigated medical treatments for RLS. The improvement is immediate and often very dramatic. The DAs consistently demonstrate dramatic improvement in PLMS but modest or no improvement in other sleep parameters. No direct evidence favors any particular DA. Rotigotine patch, pramipexole, and ropinirole are best studied, and all have level 1 evidence supporting their use LEVEL 1.[1-4] The dopamine precursor levodopa also effectively treats RLS and may have a more rapid onset of action. However, several comparative studies have favored DA over levodopa.

Immediate-release oral DAs work best if administered at least 90 minutes before the onset of symptoms. The effect is immediate, so titration to the smallest effective dose can be fairly rapid. Based on pharmacokinetics, many people may benefit from more than one dose despite the formal indications, which recommend dosing 1 to 3 hours before bed. Extended-release preparations of pramipexole and ropinirole are also effective but have not been formally studied. Nausea, sedation, and impulse control disorders can occur, but hallucinations and hypotension

FIGURE 78.1 Algorithm for restless legs syndrome (RLS) treatment.

rarely occur in RLS, making these drugs better tolerated in RLS compared to Parkinson disease. Any patient started on a dopamine drug should be warned about the potential of developing impulsive behavior such as pathologic gambling, shopping, or sexual behavior.

Despite their initial dramatic effect in treating RLS, the long-term use of DAs and levodopa is limited by the occurrence of augmentation, a paradoxical worsening of RLS which occurs in the setting of long-term DA or levodopa usage for RLS. Worsening in augmentation consists of earlier onset of RLS symptoms, involvement of previously unaffected body parts such as the arms, decreased relief of the urge to move offered by movement, or an increased intensity in RLS symptoms like the urge to move. Levodopa may be associated with the highest rates of augmentation

TABLE 78.4 Medications and Doses Used for Restless Legs Syndrome (RLS)

Drug	Amount per Dose (mg)	Duration of Effect (h)	Comment
Dopaminergics: immediate effect, considered first-line therapy			
L-Dopa	100-250	2-6	Positive class 1 trials, fast onset, can use as needed; highest augmentation rates limit the use of L-Dopa, and therefore, it is rarely used for RLS.
Pramipexole	0.125-1	5-12	Positive class 1 trials, commonly used, slower onset but longer duration, extended release available; doses should not exceed 1.0 mg as higher doses may indicate augmentation.
Ropinirole	0.25-4	4-8	Positive class 1 trials, extended-release preparations available; doses should not exceed 4.0 mg as higher doses may indicate augmentation.
Rotigotine	1-4	24	Positive class 1 trials, commonly used patch preparation; doses should not exceed 4.0 mg as higher doses may indicate augmentation.
Pergolide	0.125-1	6-14	Well studied (class 2) but seldom used due to risk of cardiac valve fibrosis and other possible ergot AE
Apomorphine	1-3	1	Injection of short-acting powerful drug, rarely used, anecdotal PRN use
Cabergoline	0.25-2	>24	Longest acting but may have same AEs as other ergot DAs
Bromocriptine	5-20	4-6	Rarely used in RLS
Opioids: Numerous opioids are used.			
Methadone	2-15	8-12	Open label data only, very good long-term tolerability and efficacy, several-day latency to benefit
Hydrocodone	5-10	4-10	Faster acting, shorter duration
Oxycodone	5-20	5-10	Best studied opioid; oxycontin is preferable at a dose of 10-20 mg
Buprenorphine	2-4	5-12	Long-acting opioid
α2δ Blockers			
Gabapentin	300-1,200	4-8	Small controlled trials; may help painful component of RLS; can be dosed nightly or once in the evening and also at night if there are evening plus nighttime symptoms
Pregabalin	50-300	6-12	Positive class 1 and 2 trials
Gabapentin enacarbil	600-1,800	8-16	Gabapentin prodrug with better absorption/bioavailability; positive class 1 trials, approved in the United States
Iron Supplementation: Can be effective both with normal or serum ferritin levels.			
Oral iron	>50	[a]	No specific iron salt superior, titrate up as tolerated; minimal data of efficacy
IV iron	1,000	[a,b]	Usually not repeated before 3 months, several-day latency to benefit, long-term safety unknown, patients with normal serum ferritin equally responsive. Anecdotal evidence favors iron dextran preparations.

Abbreviations: AE, adverse events; DAs, dopamine agonists; IV, intravenous; PRN, as necessary; RLS, restless legs syndrome.
[a]Iron treatment does not have an effect which lasts hours, rather maintaining appropriate iron levels may decrease the frequency (days per week) or intensity of RLS symptoms.
[b]Some patients find with IV iron that the therapeutic effects which make RLS less frequent and severe lasts weeks to months.

with one study showing that 91% of patients on levodopa for RLS developed definite or probable augmentation over an average period of 2.7 years. For this reason, levodopa is rarely used to treat RLS. Augmentation rates are also high for the DAs, ropinirole and pramipexole, and are estimated to occur at rates of 8% per year. This is particularly problematic as severe RLS requires lifelong medical treatment. Risk factors for augmentation include low serum ferritin, high dose of a dopaminergic, severe RLS, and long duration of treatment. For this reason, the treatment of RLS with a DA, especially when used over long periods of time (more than 4-5 y) should be done with caution. The maximum doses of dopaminergic medication should not be exceeded (see Table 78.2), and it should be noted that these dose maximums are far lower than those used to treat Parkinson disease.

Drugs that bind to the α2δ subunit of the voltage-dependent calcium channel also improve RLS and are currently favored over the DAs as there is no concern for the development of augmentation. As a class, they seem to improve International Restless Legs Scale scores similarly to DA; however, sleep studies show less improvement in PLMS but better sleep architecture. Gabapentin is the least studied but shows benefit. The gabapentin enacarbil sustained-release tablet is a novel preparation that is absorbed much more effectively in the gastrointestinal tract and can achieve higher and more sustained serum levels

of gabapentin. Multiple large class 1 trials have demonstrated efficacy, and gabapentin enacarbil is approved for treatment of RLS in multiple countries LEVEL 1.[5,6] Pregabalin is also effective in high-quality studies but is not approved by regulatory agencies.

Opioid medications, also known as *narcotics*, have long been known to successfully treat RLS. Open-label trials consistently demonstrate good initial and long-term results, with relatively little tolerance, dependence, or addiction. Low-dose methadone especially shows excellent long-term efficacy and tolerability. However, only oxycodone has been evaluated in a placebo-controlled multicenter trial. Prolonged-release oxycodone-naloxone was shown to be effective in treating severe RLS which was inadequately controlled with nonopioid medications LEVEL 1.[7] It should be said that in practice, oxycodone-naloxone is rarely used to treat RLS, rather short-acting oxycodone or long-acting oxycodone is more commonly used to treat RLS. Opioid medications are usually reserved for treatment of severe refractory RLS, especially when augmentation has taken place on a dopaminergic agent.

Augmentation occurs in RLS patients who have been treated with a DA or levodopa over a long period of time. The treatment of augmentation includes decreasing the dose or eliminating the DA. Doing this will lead to a temporary severe worsening of RLS, and after approximately 2 to 6 weeks, RLS becomes less severe and less bothersome during the day. Treatment of augmentation can also be achieved by switching form a short-acting DA (eg, ropinirole) to a longer acting DA (eg, rotigotine patch). However, even on a long-acting DA, there is risk of developing augmentation.

Both oral and intravenous iron are effective in treating RLS. A randomized double-blind, placebo-controlled study in patient with moderate to severe RLS with normal or low serum ferritin found that ferrous sulfate 325 mg orally twice daily improved RLS to a greater degree than placebo LEVEL 1.[8] Oral iron, however, can have limitations related to absorption and tolerance. In contrast, the administration of high-dose intravenous iron can dramatically increase serum ferritin levels. Intravenous iron comes in several different preparations. There is evidence from open-label studies for the efficacy of low molecular weight iron dextran in the treatment of RLS. Low molecular weight iron dextran can be given safely in a single infusion of 1,000 mg or in four weekly 250-mg infusions. There is level 1 evidence to support the use of the intravenous iron preparation, ferric carboxymaltose, at a dose of 500 mg split into two doses for the treatment of RLS LEVEL 1.[9] Intravenous iron sucrose may be effective in the treatment of RLS.

Numerous other agents including other antiepileptic medications, benzodiazepines, clonidine, baclofen, tramadol, and magnesium have been reported to help RLS but suffer from limited data and cannot be recommended as either first- or second-line therapy. Physical measures that increase activity or create a sensory stimulus can also improve RLS but are often problematic when one desires sleep.

OUTCOME

Severity of RLS varies greatly across cases. Although up to 10% of Western European and North American populations have RLS at any degree or frequency, about 2% to 4% of these populations have clinically significant RLS, 2 times per week or more and causing some amount of distress. By far, the symptom which bothers RLS patients the most is the disruption of sleep. When RLS is severe, sleep onset can be vastly prolonged, and sleep may also be interrupted numerous times in the middle of the night. As sleep is adversely effected in RLS, the disease can negatively impact all aspects of life, including social, occupational, physical, and mental aspects. These adverse consequences are stressed in updated RLS diagnostic criteria as put forth by both the American Academy of Sleep Medicine and also the International Restless Legs Syndrome Study Group. Not surprisingly, depression is highly comorbid with RLS, occurring at a rate 2 to 4 times higher than in age-matched individuals without RLS. Persons with RLS are more likely in their lifetime to have had a suicide plan or attempt compared to age-matched and demographically matched controls without RLS. The RLS also results in decreased work productivity as those with RLS have more work absenteeism and more hospitalization than persons without RLS. The RLS may also confer increased cardiovascular burden as those with RLS have been found to have increased incidence of myocardial infarction, stroke, and hypertension. This increased cardiovascular burden may be more pertinent to persons with secondary than primary RLS.

The Dystonias 79

Hyder A. Jinnah

KEY POINTS

1. Dystonia is not a single disease entity. It is a heterogeneous group of disorders that share certain features. The fundamental shared feature is excessive muscle contractions leading to involuntary abnormal movements and/or postures.
2. The many varied clinical manifestations of dystonia are classified according to four main dimensions, which include age at onset, body region affected, temporal aspects, and whether or not dystonia is combined with other neurologic or medical features.
3. The causes for dystonia also are heterogeneous. The majority of cases are idiopathic, but there are many known etiologies, both inherited and acquired.
4. Many effective treatments are available including oral medications, botulinum toxin injections, and surgical procedures.

INTRODUCTION

Defining Features of Dystonia

Oppenheim described a series of patients in 1911 who had reduced muscle tone (hypotonia) when they were resting but exaggerated muscle tone (hypertonia) with any attempted movement. He viewed the fundamental problem as a defect in the regulation of muscle tone; hence, the term *dys-tonia*. Since then, *dystonia* has become an umbrella term that includes a number of related conditions. Dystonia is no longer viewed primarily as a disorder of muscle tone. Instead, an international panel of experts agreed to the following definition:

> Dystonia is a movement disorder characterized by sustained or intermittent muscle contractions causing abnormal, often repetitive movements, postures, or both. Dystonic movements are typically patterned, twisting, and may be tremulous. Dystonia is often initiated or worsened by voluntary action and associated with overflow muscle activation.

This definition encompasses a broad range of abnormalities. The physical appearance of dystonic movements depends on the distribution of muscles involved and the strengths of individual muscle contractions. The mildest expressions appear as only subtle exaggerations of otherwise normal movements. Moderately severe expressions appear as movements that are cramped, stiff, twisting, and sometimes jerky. In the most severe expressions, dystonia can appear as fixed postures or deformities with severe disability. These movements may occur in nearly any region of the body.

Although dystonic movements are often slow and sustained, they can sometimes be rapid and jerky. Whether slow or fast, they tend to follow a recurring pattern. Dystonic movements are usually worsened by voluntary action, a phenomenon that is termed *action dystonia*. In some cases, abnormal movements emerge only with very specific actions, and the term *task-specific dystonia* is used. Dystonic movements are often accompanied by overflow muscle activation, a phenomenon that refers to activation extraneous muscles that are not needed for a movement. There often is something an affected individual can do to suppress the abnormal movements, such as touching the cheek in cervical dystonia or touching the brow in blepharospasm. This phenomenon has variably been termed *geste antagoniste* or *sensory trick* or *alleviating maneuver*. The geste can be a very helpful diagnostic clue when it is present because it is relatively unique to dystonia.

Discrimination of Dystonia From Related Disorders

Dystonia can be discriminated from other movement disorders by several features (Table 79.1). The movements of chorea are typically random, fluid, and more often rapid. In comparison, dystonic movements tend to be more patterned, less fluid, and more often slower than chorea. However, dystonia and chorea may be combined, and distinctions between them can be difficult to define. Motor tics are often patterned, and they sometimes can be relatively slow and twisting. However, dystonic movements lack the premonitory urge or the voluntary suppressibility of tics. Dystonic movements can sometimes be rapid and repetitive, resembling tremor. However, unlike more common tremors, dystonic tremors tend to be jerky and irregular in their rate and amplitude. Dystonic jerking and dystonic tremors also have a *null point*, a specific position where the abnormal movements abate or disappear.

The increased muscle tone of dystonia must be discriminated from other disorders of hypertonia (Table 79.2). Increased muscle tone in spasticity is more prominent in extensors compared with flexors, there is a rate-dependent increase in tone when the limb is passively moved, and there are usually accompanying corticospinal signs such as hyperreflexia and the extensor toe reflex. Muscle tone in dystonia increases with voluntary action, but it is usually normal or occasionally reduced at rest. In dystonia, tone is not more prominent in extensor muscles, there is no rate-dependent increase in tone with passive flexion, and there is no spastic catch. In rigidity, there is a waxy increase in extensor and flexor muscle tone with passive movement, no rate dependence, and often coexisting cogwheeling. Tone in rigidity is not significantly affected by action or rest. Paratonia refers to the inability of some subjects to fully relax when tone is tested. Some patients involuntarily aid the examiner during movements

TABLE 79.1 Distinguishing Dystonia From Related Movement Disorders

Clinical Feature	Dystonia	Chorea	Athetosis	Tremor	Tic	Myoclonus
Sustained muscle contractions or postures	Often	No	No	No	Occasionally	No
Movements are worsened with action	Often	No	No	Sometimes	No	Rarely
Movements are task specific	Often	No	No	Sometimes	No	Rarely
Overflow to extraneous muscles	Often	Sometimes	No	No	Sometimes	No
Movements are patterned	Often	No	No	Yes	Yes	Sometimes
Movement speed	Slow or fast	Medium to fast	Slow to medium	Medium to fast	Slow or fast	Very fast
Movements appear flowing	No	Yes	Yes	No	Occasionally	No
Movements have a twisting quality	Often	No	No	No	Occasionally	No
Movements have a premonitory urge	No	No	No	No	Yes	No
Movements are suppressible	No	No	No	No	Yes	No
Movements have a null point where they abate	Often	No	No	Sometimes	No	No
Geste antagoniste	Often	No	No	No	No	No

(mitgegen, or "go with"), leaving the impression of reduced or normal tone. Others involuntarily resist passive movements (gegenhalten, or "go against"), leaving the impression of increased tone. Both forms of paratonia often occur in association with dementia but may occur in cognitively normal children and adults too. Although each of these abnormalities of muscle tone can occur in isolation, they can also be combined in the same individual. Cerebral palsy is an example where there often are varying combinations of spasticity, dystonia, and rigidity.

Additional Relevant Terminology

There are a number of additional terms in common usage (Table 79.3). Dystonia is considered a disorder of a network of brain regions that control movements. However, excessive muscle contractions leading to abnormal movements or postures resembling dystonia can sometimes be seen in disorders of the spinal cord (eg, stiff person syndrome), peripheral nerves (eg, neurotonia), or muscles (eg, myotonia). Abnormal postures can also result from defects in the bones and joints (eg, joint contractures). The movements or postures associated with these other disorders can resemble dystonia, but the term *pseudodystonia* is used to discriminate them from dystonia caused by the brain's motor network. Some examples of pseudodystonias are listed in Table 79.4.

The term *dyskinesia* literally means *abnormal movement*. It is an umbrella term that encompasses all abnormal movements including dystonia. By convention, there are some more specific types of dyskinesia, such as *tardive dyskinesia* caused by exposure to neuroleptics. Another more specific type of dyskinesia is *levodopa-induced dyskinesia*. In both tardive dyskinesia and levodopa-induced dyskinesia, dystonia may be part of the syndrome along with other abnormal movements.

There also are a number of terms that juxtapose the word *dystonia* with another word. The term *myoclonus-dystonia* refers to a syndrome in which both myoclonus and dystonia occur together. The term *myoclonic dystonia* refers to dystonic movements that resemble myoclonus because movements are sudden and shock-like. The term *dystonic tic* refers to tics that have a dystonic appearance by virtue of their slow, sustained, or twisting quality. A motor seizure where abnormal tonic movements resemble dystonia is sometimes called a *dystonic seizure*. The term *spastic dystonia* refers to the combination of spasticity with dystonia, as in cerebral palsy. Although these hybrid terms are in common usage, it is the opinion of this author that they are best avoided when talking to patients or other individuals who lack expertise

TABLE 79.2 Distinguishing Dystonia From Other Hypertonias

Clinical Feature	Dystonia	Spasticity	Rigidity	Paratonia
Muscle tone increases with voluntary action	Yes	No	No	Sometimes
Muscle tone decreases at rest	Yes	No	No	Sometimes
Hypotonia at rest	Sometimes	No	No	No
Rate-dependent increase in muscle tone with passive flexion	No	Yes	No	Yes
Muscle tone is greater in extensors than flexors	No	Yes	No	No
Baseline abnormal postures	Variable depending on muscle involvement	Classical postures dominated by flexors	Often slight flexion	No
Additional helpful features	Geste antagoniste	Corticospinal signs	Cogwheeling	Associated often with dementia; tone normalizes with distraction

TABLE 79.3 Glossary of Dystonia Terms

Term	Explanation
Apraxia of eyelid opening	Difficulty opening the eyes without overt eye spasms, caused by failure of palpebral muscles to relax
Camptocormia	Forward bending of the spine, sometimes caused by dystonia or orthopedic issues
Dyskinesia	A generic term that literally means "abnormal movement"
Dystonic seizure	Seizure with tonic and sometimes twisting movements that mimic dystonia
Dystonic tic	Tic with tonic and sometimes twisting movements that mimic dystonia
Dystonic tremor	Dystonia with rapid, repetitive, and rhythmical movements that mimic tremor
Functional or psychogenic dystonia	A psychiatric disorder that includes abnormal movements resembling dystonia
Geste antagoniste	Something the patient can do to alleviate their dystonia; also known as *sensory trick* or *alleviating maneuver*
Mirror movements	Voluntary movements on one side of the body provoke similar involuntary movements on the opposite side of the body
Myoclonic dystonia	Dystonic movements with a very rapid and jerky quality mimicking myoclonus
Myoclonus-dystonia	Syndrome that combines both myoclonus and dystonia
Oculogyric crisis	Involuntary conjugate version of the eyes, usually upward and laterally
Opisthotonus	Backward arching of the trunk, from dystonic truncal extensor muscles
Overflow	Contractions of muscles for a movement spread to nearby muscles that are not required
Pisa syndrome	Sideways bending of the trunk, sometimes caused by dystonia or orthopedic issues
Pseudodystonia	Abnormal movements or postures not resulting from the brain's motor network
Spastic dystonia	Syndrome that combines spasticity with dystonia, such as cerebral palsy
Striatal toe	Extensor movement of the great toe that closely resembles the Babinski reflex; also known as *dystonic toe*
Tardive dystonia	A subtype of tardive dyskinesias caused by dopamine receptor antagonists
Task-specific dystonia	Dystonia that is triggered only by a specific task, such as writing

in neurology because they readily lead to confusion regarding whether the abnormal movements being described are a type of dystonia, some other movement disorder, a combination of abnormal movements, or a named syndrome.

Classification of Dystonia Subtypes

The modern definition of dystonia encompasses a large group of abnormal movements that are very heterogenous in terms of their clinical manifestations and underlying causes. For practical reasons, it is useful to have a simple strategy to lump and split this large group into smaller subgroups. The dystonias are currently grouped according to two main axes. Axis I addresses clinical manifestations, and axis II addresses etiologies.

TABLE 79.4 Examples of Some Pseudodystonias

Orthopedic Defects	Examples
Arthritic joint deformities	Abnormal finger postures Abnormal wrist postures
Joint contractures	Dupuytren hand Erb deformity Congenital muscular torticollis
Joint subluxations	Atlanto-axial joint Shoulder joint Hip joint
Vertebral abnormalities	Compression fractures Klippel-Feil anomaly Scoliosis
Neuromuscular Defects	**Examples**
Defects in spinal inhibition	Stiff person syndrome Tetanus
Head drop due to neck weakness	Motor neuron disease Myasthenia gravis Myopathy
Muscle hyperexcitability	Myotonia congenita Paramyotonia congenita
Neuromyotonia	Isaac syndrome
Behavioral Compensations	**Examples**
Head tilt	Ocular misalignment Vestibular imbalance
Pain guarding behavior	Abdominal cramping Protected hand/arm postures

Axis I: Clinical Manifestations

The clinical manifestations are classified according to four factors (Fig. 79.1). The first factor is the age when dystonia started. The age groups are divided according to standard ages used for many other disorders and include infancy, childhood, adolescence, and early and late adulthood. Age at onset is important because early-onset cases are more likely to progress compared to cases that emerge first in older adults. The early-onset cases are also more likely to have a discoverable cause, compared to most late-onset cases where a cause typically cannot be found.

The second factor is the distribution of the body affected with dystonia. The most common manifestation is focal dystonia, which affects one region of the body. Typical examples include cervical dystonia (neck muscles), blepharospasm (orbicularis oculi and associated muscles of the upper face), laryngeal dystonia (also known as *spasmodic dysphonia*), and hand dystonia (eg, writer's cramp). Segmental dystonia involves at least two contiguous regions. A common example is Meige syndrome, where there is involvement of the upper and lower face and sometimes the jaw and tongue. Multifocal dystonia involves at least two noncontiguous regions. An example might be blepharospasm combined with writer's cramp. Generalized dystonia involves a broader distribution of muscles. By convention, generalized dystonia must include the trunk and at least two other body regions. Hemidystonia can be viewed as a subtype of generalized dystonia when it involves the trunk and ipsilateral arm and leg.

The third factor that is useful in classifying the dystonias involves variations in the severity of dystonia over time.

FIGURE 79.1 Classification of the dystonias.

These temporal changes include the long-term evolution over years because dystonia may be relentlessly progressive, it may evolve in a stepwise fashion, or it may remain static. The temporal changes also include short-term changes, such as the diurnal variations with worsening each evening that are typical of dopa-responsive dystonia or transient attacks of dystonia typical of the paroxysmal dyskinesias.

Finally, the last factor is whether dystonia is isolated (pure) or combined with other neurologic or medical problems. In the context of the dystonia classification system, the term *isolated* refers only to whether or not dystonia is the sole problem. The term *isolated* does not refer to dystonia limited to a single body region. More than one region may be involved in isolated dystonia, as in segmental or generalized dystonia. Because tremor occurs in at least half of all patients with dystonia, the diagnosis of isolated dystonia may include accompanying tremor. Other accompanying features are important because there are numerous well-recognized syndromes where dystonia is combined with another movement disorder such as parkinsonism, ataxia, or myoclonus. There also are numerous well-recognized syndromes where dystonia is combined with other neurologic (eg, neuropathy, retinopathy, epilepsy) or medical (eg, hepatic or hematologic) problems.

Axis II: Etiologies

Known etiologies for dystonia are grouped according to two main factors (see Fig. 79.1). The first factor is based on neuropathology. In the majority of dystonias, overt structural defects are absent. In rare cases, there may be evidence that dystonia is caused by a focal lesion or a neurodegenerative process. Some of these lesion-based dystonias are described further in the following text.

The second factor is based on whether dystonia is inherited or acquired. The majority of dystonias are sporadic, and a cause cannot be identified. In some cases, there is evidence for an acquired or inherited cause. Examples of some of the acquired causes are listed in Table 79.5 and described further in the following text. The inherited subgroups include the usual common patterns of dominant, recessive, sex-linked, and mitochondrial. Some of the more common inherited causes for dystonia also are described further in the following text.

Axes I and II are not mutually exclusive and were envisioned to work together. The goal of defining the four factors of axis I is to emphasize the clinical features that are most relevant for delineating dystonia syndromes, which often have specific etiologies described by axis II.

EPIDEMIOLOGY

Isolated Dystonia Syndromes

Isolated dystonia, previously known as *primary dystonia*, refers to a group of disorders where dystonia occurs in the absence of other relevant neurologic or medical problems. Estimates for the prevalence of isolated dystonia vary widely due to methodologic differences. Meta-analyses of the most rigorous studies place the overall prevalence of all isolated dystonia syndromes combined at approximately 16 cases per 100,000 population. The vast majority of these cases are adult-onset focal and segmental dystonias, with an overall prevalence of approximately 15 cases per 100,000 population. Among these, cervical dystonia is the most common, followed by blepharospasm, and then upper limb dystonias. Oromandibular and laryngeal dystonias are less common. The early-onset generalized dystonias consist of a very small fraction of total cases with isolated dystonia.

Although the dystonias are considered rare disorders, it is widely believed that their prevalence is underestimated because of poor recognition of the many varied manifestations. By comparison, there are more definitive data on the prevalence of essential tremor and Parkinson disease. Meta-analyses of the most rigorous epidemiologic studies reveal an overall prevalence per 100,000 population of approximately 450 cases for essential tremor and 113 for Parkinson disease. For both tremor and Parkinson disease, prevalence varies by age. For Parkinson disease, for example, age-adjusted prevalence estimates per 100,000 population are 41 cases (ages 40-49 y), 107 cases (ages 50-59 y), 428 cases (ages 60-69 y), 1,087 cases (ages 70-79 y), and 1,903 cases (age >80 y).

Other Syndromes With Dystonia

There are many disorders where dystonia is combined with other neurologic problems. The epidemiology of dystonia for most of these disorders has not been methodically evaluated in large-scale studies, although it is likely that the combined prevalence of dystonia in these mixed disorders is higher than in the isolated dystonia syndromes.

For example, dystonia is a common accompanying feature of Parkinson disease. In the most methodical studies, 30% to 40% of patients with Parkinson disease have dystonia at some

TABLE 79.5 Some Acquired Etiologies for Dystonia

Vascular Etiologies	**Autoimmune-Paraimmune**
Antiphospholipid syndrome	Behçet disease
Arteriovenous malformations	Multiple sclerosis
Hemorrhagic stroke	PANDAS
Ischemic stroke	Paraneoplastic syndromes
Subarachnoid hemorrhage	Sjögren syndrome
Vascular malformations	Systemic lupus erythematosus
Vasculitis	Sydenham chorea
Toxins	**Infections**
3-Nitropropionic acid	Abscess
Carbon monoxide	Encephalitis
Carbon disulfide	HIV/AIDS
Cyanide	Subacute sclerosing panencephalitis
Disulfiram	**Others**
Manganese	Brain tumors
Methanol	Cerebral palsy
Wasp sting	Hypoparathyroidism
Medications	Kernicterus
Anticonvulsants	Tics and Tourette syndrome
Antidepressants	Trauma
Calcium channel blockers	
Dopamine receptor antagonists	
Ergots	
Fenfluramine	
Levodopa	

Abbreviation: PANDAS, pediatric autoimmune disorders associated with anti-streptococcal antibodies.

point in their illness. In 10% to 15% of these patients, dystonia is the main problem at disease onset. Dystonia also occurs later in the disease as a complication of levodopa treatment. Dystonia is most common during trough periods between doses and affects 10% to 20% of patients. Dystonia is even more common in the Parkinson imitator disorders such as corticobasal syndrome, progressive supranuclear palsy, and multiple system atrophy.

Another disorder where dystonia is common is cerebral palsy, which is estimated to have an overall prevalence of approximately 150 to 400 cases per 100,000. In the most methodical studies encompassing all types of cerebral palsy, approximately 80% have dystonia. In cerebral palsy, dystonia is most often combined with varying degrees of spasticity or rigidity, although dystonia can be the dominant movement disorder in 10% to 15% of children with the dyskinetic subtype of cerebral palsy.

Dystonia also occurs in numerous other neurologic disorders. Dystonia is common in Huntington disease, and dystonia often dominates the movement disorder in juvenile-onset cases. Dystonia also is common in the spinocerebellar ataxias, and in some cases, dystonia is the dominant movement disorder. Dystonia also is an accompanying feature of tardive syndromes caused by neuroleptics, and the term *tardive dystonia* is used to refer to those in which dystonia is the main problem. The prevalence of dystonia in these many different disorders has not been well characterized.

PATHOBIOLOGY

Anatomic Underpinnings of Dystonia

Dystonia is currently viewed as a disorder of a motor network that involves the basal ganglia, cerebellum, sensorimotor cortex, and probably other regions, too. Available evidence suggests that different types of dystonia may arise from defects in different areas of the motor network. For example, there is compelling evidence that the basal ganglia are responsible for some types of dystonia, such as dopa-responsive dystonia, which is caused by inherited defects in the synthesis of dopamine, a critical neurotransmitter of the basal ganglia. On the other hand, the cerebellum has been implicated in other types of dystonia, for example, cervical dystonia. Other studies have implicated the sensorimotor cortex, thalamus, and midbrain or brainstem.

Most of the regions implicated in dystonia are interconnected in a "motor network." The challenge in understanding the neuroanatomic substrates for dystonia has been to elucidate how the motor network is disrupted to cause different types of dystonia (Fig. 79.2). Different types of dystonia might originate in individual nodes of the network. Alternatively, dystonia might originate from combined dysfunction of two nodes, the so-called "two-hit hypothesis." Finally, dystonia might arise from defects in the communication among the nodes.

FIGURE 79.2 The functional neuroanatomy of cervical dystonia (CD). Although focal lesions are uncommon causes of cervical dystonia, lesions have been described for different parts of the brain in different patients, with some examples shown in the top row. When these different lesions for different patients are mapped onto a shared atlas of brain connectivity, a network of interconnected regions becomes apparent. This network involves the cerebellum, basal ganglia, and sensorimotor cortex. (Modified from Daniel DT, Joutsa J, Darby RR, et al. Network localization of cervical dystonia based causal brain lesions. *Brain*. 2019;142[6]:1660-1674.)

Understanding how the motor network is affected in different types of dystonia is important because it has direct implications for neurosurgical treatments. Notably, surgical interventions targeting different regions of the basal ganglia provide significant relief for some types of dystonia, such as early-onset generalized dystonia associated with defects in the *TOR1A* gene. However, targeting the same region is not effective for other types of dystonia, such as rapid-onset dystonia parkinsonism caused by defects in the *ATP1A3* gene. Presumably, alternative targets need to be considered in such cases.

Physiologic Underpinnings of Dystonia

Muscle Activity

A core defect underlying dystonia is excessive and often repetitive contraction of muscles. It is often claimed that a cardinal feature of dystonia involves cocontraction of agonist and antagonist muscles. However, cocontraction of antagonistic muscles is not universal in dystonia. Instead, the cardinal feature of dystonia is muscle overcontraction leading to excessive force, or spread of contractions to nearby muscles. When this spreading involves antagonistic muscles, then cocontraction of antagonists may occur.

Electromyography (EMG) can be used to detect excessive and repetitive muscle contractions, spreading, and cocontraction of antagonistic muscles. However, these EMG findings are not specific to dystonia. Excessive and repetitive muscle contractions can be seen with voluntary overcontractions in normal individuals or stiff person syndrome. Cocontraction of antagonistic muscles can be seen with voluntary isometric contractions in normal individuals. Because no EMG feature is specific to dystonia, EMG is not routinely used as a diagnostic tool. However, EMG can sometimes be used to rule out other disorders, including some of the pseudodystonias. The EMG can also be valuable for localization of muscles that are most appropriate to inject with botulinum toxin for treatment.

Neuronal Physiology

Most forms of dystonia are not associated with overt structural abnormalities of the brain, and only subtle morphologic changes of individual neurons are found. There is limited information regarding neuronal function in human dystonia. Quantitative electroencephalography has revealed abnormal oscillatory activity in the cerebral cortex of patients with isolated dystonia. Recordings of local field potentials during deep brain stimulation (DBS) surgery have revealed abnormal activity in the basal ganglia and thalamus from several types of dystonia, too. The biologic basis for this activity and how it may contribute to cause dystonia are not well understood. Similar abnormalities have been reported for patients with psychogenic (functional) dystonia and other movement disorders, raising questions regarding whether it may be a consequence of abnormal movement rather than a cause.

Because of the challenges associated with physiologic evaluation of neurons in the human brain, animal models have been explored. A number of experimental manipulations in animals can produce abnormal movements that have characteristics typical of human dystonias (Fig. 79.3). Several animal studies have pointed to abnormalities of the basal ganglia, whereas others have pointed to the cerebellum. For example, mouse models associated with defects in the *TOR1A* gene demonstrate abnormal dopamine release from nigrostriatal afferents in the basal ganglia along with abnormalities in corticostriatal and cholinergic interneuron activity. In primate models, electrophysiologic recordings have pointed to an

FIGURE 79.3 Animal models of dystonia. **A:** Cervical dystonia in a cat caused by injection of a glutamate agonist into the midbrain tegmentum. **B:** Cervical dystonia in a rhesus monkey caused by electrolytic lesions of the brainstem reticular formation. Generalized dystonia has been observed in rodent species including hamsters **(C)**, rats **(D)**, and mice **(E)**. (Modified from Jinnah HA, Prudente CN, Rose SJ, Hess EJ. The neurobiology of dystonia. In: Johnston MV, Adams HP, Fatemi A, eds. *Neurobiology of Disease*. 2nd ed. New York, NY: Oxford University Press; 2016:60-74.)

imbalance between the direct and indirect pathways of the basal ganglia, or rate-dependent alterations in basal ganglia output.

Studies of other mouse models of dystonia have pointed to abnormalities of the cerebellum. One common finding in these models involves abnormal burst firing of Purkinje neurons. This phenomenon has been demonstrated in a rat model of early-onset generalized dystonia, a mouse model of paroxysmal dystonia, mouse models of rapid-onset dystonia parkinsonism syndrome, and several other genetically engineered rodent models with specific defects in the cerebellum.

Network Physiology

Three overarching conceptual models have been proposed to explain the physiologic basis for dystonia. One model proposes an imbalance between the normal inhibitory and excitatory influences in the nervous system. An impairment in normal inhibitory processes has been found in many types of dystonia and in multiple regions of the nervous system such as the cerebral cortex, brainstem, and even the spinal cord. This model is intuitively attractive because the fundamental problem in dystonia is excessive muscle contraction. However, impaired inhibition is not specific to dystonia and can be found in other neurologic disorders. These observations have led to questions regarding whether the impairment of inhibition may be a consequence of abnormal movement, rather than a cause.

Another model involves abnormalities of sensory feedback to the nervous system or abnormal integration of sensory feedback with motor output. A defect in sensorimotor integration also is intuitively attractive because of the obvious need to match motor output with sensory feedback during and after movement. Overt sensory defects are not usually detected during the routine neurologic exam in most patients with dystonia; but quantitative studies have revealed subclinical defects in spatial discrimination, the ability to detect two distinct but simultaneous stimuli that close to each other. Other studies have revealed subclinical defects in temporal discrimination, the ability to detect two distinct stimuli delivered in rapid sequence. There also is evidence for abnormal feedback from muscle spindles, which regulate muscle tone.

The third model involves neural plasticity. The nervous system is known to change its responses with experience, a phenomenon known as *adaptive plasticity*. Abnormalities of these processes (maladaptive plasticity) may occur, and abnormalities of neuronal plasticity have been documented for dystonia. This mechanism is intuitively attractive because some forms of dystonia arise from repetitive overuse or overtraining, such as task-specific dystonias. Whether this mechanism can also apply to dystonias that emerge without repetitive motor behavior remains unclear.

Developmental or Degenerative Processes

Several experts have proposed that dystonia is a developmental disorder. In fact, the majority of inherited dystonias arise during childhood, and many of the responsible genes affect neurodevelopmental mechanisms without causing any obvious neurodegenerative abnormalities.

However, there also are many subtypes of dystonia that are associated with degenerative mechanisms. Some of these degenerative disorders arise during childhood, and others arise later in adulthood. For the most common types of adult-onset dystonia, evidence for developmental or degenerative mechanisms is scarce. In these cases, some physiologic disturbance in the motor network may occur.

Etiologies for Dystonia

Idiopathic Dystonias

There are many known etiologies for dystonia, some of which are outlined in the following text. However, it is important to emphasize at the outset that the majority of cases are idiopathic, and often, a cause cannot be identified. The likelihood of finding a cause for dystonia depends on a number of factors including age at onset, family history, and nature of dystonia syndrome. A cause is more likely to be disclosed in early onset cases, especially if there is a family history. Such cases are relatively rare. In contrast, a cause is only rarely disclosed for the more common sporadic adult-onset dystonias, even after extensive diagnostic testing. For these cases, the etiology is thought to reflect a combination of genetic predisposition along with some environmental contingency.

The nature of the environmental contribution is not always apparent, although some risk factors have been identified. The best known risk factor involves highly repetitive movement, leading to a task-specific dystonia. Epidemiologic studies have identified a number of other potential risk factors, although a causal role has been difficult to establish. Women outnumber

men for many adult-onset focal dystonias such as cervical dystonia and blepharospasm. Some studies have identified prior trauma to the head or the body region affected with dystonia as a risk factor for dystonia. Dry or irritated eyes and exposure to bright light have been associated with blepharospasm. Viral or other types of laryngitis have been associated with laryngeal dystonia. Whether or not these environmental factors reflect a recall bias or they contribute to the development of dystonia remains unclear. The following text describes some of the more common dystonia syndromes that are most often idiopathic.

Cervical Dystonia

Cervical dystonia is the most common of all isolated dystonia syndromes. It is characterized by excessive involuntary contractions of muscles in the neck, leading to abnormal head postures and/or repetitive head movements (**Fig. 79.4**). Common patterns include torticollis (turning of the chin right or left), laterocollis (tilting of the ear toward one shoulder or the other), anterocollis (flexion of the chin toward the chest), and backward bending of the head (retrocollis). Less commonly, the entire head and neck may shift forward or laterally on the shoulders. Abnormal movements may be relatively tonic or more dynamic, occasionally with sudden, intermittent, and large-amplitude jerky movements of the head (spasmodic torticollis). On other occasions, movements may be lower in amplitude and regular, resulting in a head tremor. Neck and/or shoulder pain occurs in approximately two-thirds of patients.

Cervical dystonia may emerge at any age, but it is most common in adults >40 years of age. Two-thirds of cases are female. Most cases start insidiously with obvious worsening of symptoms over 3 to 12 months. In approximately 20% of cases, there is continued worsening over 5 to 10 years, with spread to nearby body regions such as the head, larynx, or upper limb.

Craniofacial Dystonia

Blepharospasm is characterized by excessive involuntary contractions of the muscles of the upper face, particularly the orbital portion of the orbicularis oculi and nearby muscles (**Fig. 79.5**). The most common manifestations are excessive blinking with superimposed spasms of eye closure bilaterally. A less common manifestation involves difficulty opening the eyes with no apparent spasms of the orbicularis oculi. This difficulty may develop following years of excessive blinking and spasms, or it may occur on its own. It has been labeled as *apraxia of eyelid opening*, although it may be a consequence of dystonia due to excessive contraction of the palpebral portion of the orbicularis oculi, preventing eyelid opening.

Blepharospasm may emerge at any age, but it is most common in adults >50 years of age. Two-thirds of cases are female. It usually begins insidiously, with irritating sensations in the eyes and excessive blinking preceding more obvious eye spasms. Approximately half of all patients will experience spread of excessive contractions to the oromandibular region over 5 years. Involvement of the lower face leads to grimacing or other movements (see **Fig. 79.5**). Involvement of the jaw leads to involuntary jaw opening, involuntary jaw closing, lateral deviation of the jaw, and/or jaw pain. Abnormal jaw movements are often

FIGURE 79.4 Cervical dystonia. Abnormal head postures seen in cervical dystonia include torticollis (**A**), laterocollis (**B**), anterocollis (**C**), and retrocollis (**D**). The majority of patients have various combinations of these abnormal postures. The common combination of laterocollis, torticollis, and anterocollis is shown in **E**. The combination of laterocollis, torticollis, and retrocollis is shown in **F**. Occasionally, the head and neck can move in opposing directions. The combination of right bending of the neck (laterocollis) and left bending of the head (laterocaput) is shown in **G**. The combination of backward extension of the neck (retrocollis) combined with forward flexion of the head (anterocaput) is shown in **H**.

FIGURE 79.5 Craniofacial dystonia. **A:** The most common abnormality in blepharospasm involves spasms of the orbital portion of the orbicularis oculi with eyes squeezing tightly closed. **B:** Apraxia of eyelid opening involves spasms of the palpebral portion of the orbicularis oculi with no apparent squeezing of the eyes, although there often is compensatory activation of the muscles of the forehead during voluntary efforts to open the eyes. **C:** Involvement of the lower face with grimacing or other facial contortions occurs in approximately 50% of patients. Rarely, the jaw may also be involved with involuntary opening, closing, or lateral deviations.

task specific and triggered by chewing or speaking. The tongue may also be involved, with excessive protrusion, retraction, rolling, sideways movements, or other abnormal movements.

Limb Dystonias

In adults, upper limb dystonias are far more common than lower limb dystonias. They are typically task specific with the most common types being writer's cramp and musicians who play string or keyboard instruments (Fig. 79.6). When they lack task specificity, the possibilities of Parkinson disease or a Parkinson imitator disorder must be considered. Unlike other focal dystonias, the limb dystonias appear to affect men and women equally.

Limb dystonias may also started at any age but are more common in adults >40 years of age. Adult-onset limb dystonia may start out with high task specificity, such as inability to write a single letter or number. This specificity may then extend over time to include difficulty with most letters and numbers. Specificity may degrade further over time to include other tasks, such as using eating utensils or buttoning a shirt. In children, limb dystonias are more common, and there is a high risk of progression toward generalized dystonia.

Laryngeal Dystonia

Laryngeal dystonia is characterized by excessive contraction of muscles in the larynx. The most common manifestation involves the adductors of the vocal cords (adductor spasmodic dysphonia) with excessive closure of the cords leading to an intermittently strained and strangled voice, along with voice breaks when there is transient complete closure of the cords. The abductors of the vocal cords are less commonly involved (abductor spasmodic dysphonia), with excessive opening of the vocal cords leading to an intermittently strained but breathy voice, also with occasional voice breaks, where there is transient opening of the cords during phonation. The spasmodic dysphonias are task specific and triggered by speaking.

FIGURE 79.6 Limb dystonias. Abnormal postures in writer's cramp may involve various combinations of the fingers, wrist, or upper arm **(A-D)**. Abnormal postures may also involve the lower limb **(E)**. Extensor posturing of the great toe **(F)**, also known as the *striatal toe* or *dystonic toe*, is a form of dystonia that is often mistaken for the Babinski sign.

Rarely, patients may have both adductor and abductor spasmodic dysphonia combined. Another rare subtype of laryngeal dystonia is breathing dystonia, where there is dystonic closure of the vocal cords during inspiration, often with stridor. Other rare subtypes of laryngeal dystonia may mimic coughing, sneezing, or hiccups. Laryngeal dystonia is frequently accompanied by vocal tremor, which is expressed as regular oscillations of laryngeal muscles leading to audible oscillations of the voice.

Segmental and Multifocal Dystonias

As noted in the preceding text, most of the adult-onset focal dystonia syndromes begin insidiously with worsening over the first few weeks or months, followed by slower progression thereafter. Spread to a contiguous region (segmental dystonia) or a remote region (multifocal dystonia) is not uncommon. The rate of spread depends on the site of origin. The 5-year risk of spread is approximately 50% for blepharospasm in adults. This 5-year risk is 10% to 20% for cervical dystonia, laryngeal dystonia, and hand dystonias.

Truncal Dystonias

Truncal dystonias are uncommon. They include backward bending (opisthotonus), forward bending (camptocormia), and sideways bending (Pisa syndrome). Scoliosis may occasionally reflect a truncal dystonia. Opisthotonic posturing in a child often is a sign of an inherited metabolic disorder. Opisthotonus in an adult raises concern for a tardive syndrome. Camptocormia and Pisa syndrome in adults are most often seen in Parkinson disease or the Parkinson imitator syndromes, although these postural defects may be due to causes other than dystonia, such as myopathy. Generalized dystonia refers to truncal dystonia accompanied by at least two other body regions.

Acquired Dystonias

Dystonia may be acquired from many different processes (see Table 79.5). Dystonia resulting from structural damage to the nervous system may be caused by focal lesions, such as vascular insults (ischemic or hemorrhagic stroke) or space-occupying lesions (tumors or abscesses). One of the more common syndromes caused by lesions is cerebral palsy, which is most often caused by perinatal hypoxic-ischemic injury to the brain. Approximately 80% of children with cerebral palsy have dystonia, most often combined with spasticity and/or rigidity. One unusual aspect of dystonia caused by focal lesions is that symptoms sometimes do not emerge immediately following the lesion. Dystonia may develop over weeks or months, and it is sometimes delayed by many years.

Dystonia also may be acquired from exposure to toxins, illicit drugs, or medications. Toxin-induced dystonia typically emerges over days or weeks, often accompanied by basal ganglia damage that can be visualized by magnetic resonance imaging (MRI). One of the more common causes of acquired dystonia is exposure to medications that block dopamine receptors. This group of medications includes both classical and atypical antipsychotics as well as medications used for gastrointestinal discomfort such as metoclopramide and prochlorperazine. These drugs can cause two different dystonic syndromes, neither of which is associated with any obvious abnormality in routine clinical neuroimaging. Acute dystonic reactions emerge within a few minutes to an hour after exposure and are typically expressed as sudden and often jerky backward or sideways bending of the head, sometimes combined with tonic upward and/or horizontal deviation of the eyes. Forced version of the eyes is sometimes called *oculogyric crisis*. Treatment requires terminating the offending drug and temporary institution of anticholinergics and/or benzodiazepines. Tardive dystonia emerges usually after several months of exposure but may emerge after shorter durations. The typical appearance involves backward bending of the head and trunk, although involvement of the face and arms may also occur.

Some studies have linked head trauma with dystonia. Others have linked trauma to other parts of the body with dystonia that may then develop in the same region. This phenomenon is sometimes called *peripheral dystonia* and is often associated with pain in the same region. Approximately half of all patients with complex regional pain syndrome will have dystonic posturing of the affected body region.

Perhaps the most common of the acquired dystonias are the task-specific dystonias. Writing and typing predispose to writer's cramp or typist's cramp. Professional speakers are predisposed to laryngeal or oromandibular dystonia. Professional musicians are at risk for developing task-specific dystonias specific to their musical instruments. A wide array of tasks appears capable of provoking task-specific dystonias (Table 79.6). In most cases, the triggering task is highly repetitive, very precise, and often performed under some type of stress such as a time constraint or need for extreme precision. Whether task-specific dystonias are entirely acquired or reflect some interaction between repetitive motor behavior and innate variables remains to be determined.

Dystonia is rarely acquired as a result of infections of the nervous system. A variety of different organisms may be responsible, including viruses, bacteria, and others. In many cases, the pathomechanism involves direct invasion and injury of specific regions in the nervous system that cause dystonia. In other cases, the pathomechanism involves immunologic responses that indirectly damage the nervous system. For example, individuals with mycoplasma pneumonia rarely develop acute striatal necrosis during the convalescent period, a phenomenon that may reflect a delayed autoimmune mechanism. Dystonia may also result from autoimmune mechanisms with no apparent preceding infection or a manifestation of a paraneoplastic process.

Some of the more challenging syndromes are psychiatric disorders that mimic dystonia. Frank malingering (feigning dystonia for secondary gain) is relatively uncommon, but unintentional

TABLE 79.7 Some Clues for Functional (Psychogenic) Dystonia

Clinical Feature	Psychogenic Dystonia	Nonpsychogenic Dystonia
Abrupt onset	Abnormalities often reach maximum severity in a short period of time, sometimes overnight.	Most have insidious progression, although some may have abrupt onset such as rapid-onset dystonia parkinsonism, acute dystonic reactions, and acute striatal necrosis.
Fixed abnormal postures	Posture is fixed and immobile, such as foot intorsion preventing walking, often from the outset.	Most are at least partially mobile, although fixed postures with contractures may occur in longstanding cases.
Change in body distribution	Abnormalities move from one area of the body to another.	Most follow a recurring pattern in the same body region, although spread to other regions may occur over months or years.
Change in type of movement	Dystonic-looking movements are sometimes replaced by other movement abnormalities such as slowing, tremor, jerking, or paresis.	Most are relatively patterned, although they may be position dependent or may combine slowness, tremor, and jerking.
Unexplained variation over time	Multiple remissions, sudden worsening or attacks of abnormal movements	Most are persistent, although they may wax and wane in severity; remissions may rarely occur, and paroxysmal phenotypes are recognized.
Suggestibility	Abnormal movements may be induced by talking about them.	Most are not suggestible, although talking about them may make them appear worse.
Intentional slowness	Movements are extremely slow and effortful when being evaluated but may appear normal at other times.	Movements may be slow, and action dystonia worsens with effort.
Nonorganic signs	Examples include functional blindness, functional sensory abnormalities, functional weakness, etc.	Functional signs are uncommon, although subjective nature of reporting can be misleading.

dystonia-like movements are common. The preferred names for these disorders have evolved over the years. In psychiatry, the *Diagnostic and Statistical Manual of Mental Disorders* (4th ed) used terms *somatoform disorder* or *somatization disorder*, but in *Diagnostic and Statistical Manual of Mental Disorders* (5th ed), the preferred terms included *conversion disorder* and *somatic symptom disorder*. Neurologists more frequently use terms such as *nonorganic dystonia* or *psychogenic dystonia* or *functional neurologic disorder*. There are several clues that point to the diagnosis of these disorders including abrupt-onset, relatively fixed, and immobile postures, changing distribution or type of abnormal movements, unexplained variation over time, "intentional" slowness, nonorganic neurologic signs, suggestibility, and others (**Table 79.7**). A history of psychiatric disorders or evidence for active psychiatric distress is helpful but not always evident. Although these clues are helpful, they are not foolproof, and diagnostic agreement is poor even among experts. However, the discrimination of these psychiatric disorders from other causes of dystonia is important because the treatment strategy is different.

Inherited Dystonias

By now, more than 100 genes have been linked with various dystonia syndromes. All together, these genes account for no more than 5% of cases, so other genetic or nongenetic contributions remain to be found. Only a small fraction of these genes typically cause isolated dystonia syndromes (**Table 79.8**). The remaining genes cause more complex syndromes that include other neurologic or medical problems (**Table 79.9**). However, most of the genes that usually cause combined dystonia syndromes may occasionally cause isolated dystonia, at least during early stages. This section summarizes some general principles. More details regarding the many specific inherited dystonia syndromes can be found in published reviews.

The increasing number of dystonia genes combined with advances in clinical diagnostic testing have stimulated revision of many traditional beliefs. For example, early studies emphasized that inherited isolated dystonias usually emerge first in childhood or adolescence. However, it is now recognized that some patients may present later during adulthood. The late-onset cases often have atypical manifestations. For example, pathogenic genetic variants in the *TOR1A* gene are typically associated with childhood-onset limb dystonia with progression to generalized dystonia. On the other hand, occasional cases develop adult-onset focal dystonia with minimal progression over time.

Another new trend has involved the diagnostic approach for the many combined dystonia syndromes. The traditional approach has emphasized the importance of delineating characteristic syndromes to guide diagnostic testing of specific genes. However, syndromes caused by different genes overlap considerably, and atypical syndromes are increasingly recognized. For example, pathologic genetic variants in the *ATM* gene are typically associated with ataxia-telangiectasia, where the most commonly recognized phenotype is ataxia and ocular telangiectasias, occasionally combined with mild dystonia. For occasional cases with *ATM* defects, dystonia may be the dominant or even the sole motor defect, sometimes without telangiectasias. Such atypical phenotypes are being increasingly recognized for many genes, making the syndromic approach to diagnostic testing increasingly challenging.

Another traditional belief has been that considering genetic causes for dystonia is important only when there is a family history. It is now better appreciated that de novo gene defects cause many sporadic cases, too, with no family history. The frequency at which sporadic cases occur depends on the gene. For some genes, up to 90% of cases are sporadic.

TABLE 79.8 Inherited Isolated Dystonias

Gene	Protein	Inheritance	Typical Age of Onset	Typical Body Distribution
ANO3	Anoctamin-3	Autosomal dominant with partial penetrance	Adulthood	Neck, with prominent tremor
CIZ1	Cip1-interacting zinc finger protein 1	Autosomal dominant with partial penetrance	Adulthood	Neck
COL6A3	α_3 Subunit of type VI collagen	Autosomal recessive	Early childhood	Neck, upper body
GNAL	G-protein subunit alpha L	Autosomal dominant with partial penetrance	Adult	Head, neck, upper body
THAP1	Thanatos-associated domain-containing apoptosis protein 1	Autosomal dominant with partial penetrance	Adolescence	Head, neck, upper body
TOR1A	TorsinA	Autosomal dominant with partial penetrance	Childhood	Upper or lower limbs, often generalized

For other genes, heritability is more obvious and less than 10% of cases are sporadic. In addition, many pathologic variants in dystonia genes are only partly penetrant, so identifying typical dominant or recessive patterns of inheritance can be a challenge. Finally, some genes are associated with very different phenotypes, even among members of the same family. As a result, identifying a clear pattern of inheritance is sometimes difficult.

One big surprise that has come from the advances in genetics has been the relevance of inherited causes for disorders traditionally considered to be acquired. For example, dystonia is common in cerebral palsy and may be the dominating feature. Cerebral palsy has been viewed for many years as a disorder that is acquired from perinatal brain injury, such as hypoxia/ischemia or hemorrhage. However, multiple studies have now demonstrated that up to 30% of cases diagnosed with cerebral palsy may have a genetic explanation.

Although each of the inherited dystonias is rare, a molecular diagnosis is becoming increasingly important for two major reasons. First, many patients move from one doctor to the next, seeking a definitive answer. This process is frustrating and expensive for both patient and clinician and has become known as the *diagnostic odyssey*. Second, there are increasing numbers of disorders for which specific treatments are available.

DIAGNOSIS

Approach to Clinical Evaluation

Patients with dystonia often complain that they have seen multiple doctors over many years prior to reaching a diagnosis. Even for the most common adult-onset focal dystonias, there is a

TABLE 79.9 Examples of Inherited Combined Dystonia Syndromes[a]

Syndrome	Phenotype	Typical Age at Onset	Some Responsible Genes	Notes
Dopa-responsive dystonia	Arm or leg dystonia with diurnal worsening each evening	Childhood through adolescence	*GCH1* is most common; less commonly *TH, SPR, PTS, PRKN*, or *PINK1*	Rare cases may emerge in adulthood; may be axial-dominant; often mistaken for cerebral palsy
Myoclonus-dystonia	Dystonia and myoclonus most often in neck or upper limbs	Childhood through adolescence	*SGCE, KCTD17, RELN*	Some cases may have myoclonus or dystonia alone; often alcohol-responsive
Dystonia-parkinsonism	Progressive dystonia combined with parkinsonism	Childhood through young adulthood	*ATP1A3, GCH1, ATP7B, SLC30A10, SLC39A14*	Includes also most of the NBIA disorders
Dystonia-ataxia	Dystonia combined with ataxia	Childhood through older adulthood	*ATM, CTX, NPC1, NPC2, POLG*, many SCA disorders	Includes also many SCA disorders
Dystonia with MRI evidence of heavy metal accumulation	Slowly progressive dystonia and parkinsonism	Childhood through young Adulthood	*ATP7B, SLC30A10, SLC39A14*	Includes many of the NBIA disorders
Rapid-onset dystonia	Acute or subacute onset of dystonia, often involving bulbar muscles, often combined with parkinsonism	Childhood or adolescence	*ATP1A3, GCHD, MUT, PCCA, PCCB, SLC19A3*	Often triggered by physical or psychological stress
Paroxysmal dyskinesias	Sudden onset of mixed abnormal movements with dystonia superimposed on a normal or near-normal baseline	Childhood through adolescence	*PRRT2, MRI, SLC2A1*	Often mistaken for epilepsy

Abbreviations: MRI, magnetic resonance imaging; NBIA, neurodegeneration with brain iron accumulation; SCA, spinocerebellar ataxia.
[a]This is a partial list of some combined dystonia syndromes. More complete lists can be found in prior reviews.

delay of 2 to 10 years from the onset of symptoms to diagnosis. The delay is often longer for less common types of dystonias. The main reason for the delay is poor recognition of the many different manifestations of dystonia. The diagnosis is easy for the most severe manifestations where multiple regions of the body are affected by twisting movements and abnormal postures. The diagnosis takes longer for less severe or less common syndromes.

Once a diagnosis of dystonia is made, it is important to delineate the subtype. Many diagnostic algorithms have been published, each focusing on certain subgroups of dystonia. Universal diagnostic algorithms are difficult to use because of the wide variety of clinical manifestations and etiologies. The diagnostic approach must be customized for each patient, but there are some helpful general principles.

The diagnostic approach starts with a careful clinical history and examination aimed at complete delineation of the dystonia syndrome, with attention to each of the factors relevant to clinical classification: age at onset, body distribution, temporal evolution, and any associated findings. Delineating the clinical syndrome helps to guide the laboratory workup and treatment. The application of additional tests is summarized in the following text.

Diagnostic Imaging

The value of clinical imaging depends on the nature of the dystonia syndrome. The most common dystonia syndromes are the adult-onset focal dystonias that arise after 40 years of age. They include cervical dystonia, blepharospasm, task-specific hand dystonia, and laryngeal dystonia. In these cases, brain imaging is usually unrevealing, so it often is not conducted. For laryngeal dystonia, imaging the vocal apparatus via laryngoscopy can be useful for excluding structural defects that may cause voice problems mimicking dystonia. For adult-onset hemidystonia or generalized dystonia, brain MRI is important to exclude structural causes. Brain MRI also is valuable in adults when the dystonia syndrome includes other features such as ataxia or parkinsonism and in adults with rapid worsening of symptoms. Imaging of dopamine systems is not usually conducted unless there is concern that dystonia is an early manifestation of Parkinson disease.

For dystonias that begin in younger individuals (<40 y of age), brain imaging is valuable for virtually all cases because it can guide further diagnostic workup. For example, a history of difficult birth together with periventricular leukomalacia on MRI raises concern for cerebral palsy. The discovery of white matter abnormalities may raise concern for an autoimmune disorder or an inherited disorder of white matter. Lesions of the basal ganglia can point a mitochondrial disorder, neurodegeneration with brain iron accumulation, or an immune process. These neuroimaging signs are useful when they are found, but for many patients with dystonia, imaging may be normal, or there may be abnormalities that are nonspecific. In these cases, additional laboratory investigations may be required.

Routine Laboratory Investigations

For all age groups, routine hematology or chemistry studies are only rarely helpful. However, specific tests may be useful in certain circumstances. Similar to imaging studies, the types of laboratory studies depend on the nature of dystonia syndrome. For example, testing serum ceruloplasmin is mandatory for all early-onset dystonias to rule out Wilson disease because it is treatable. On the other hand, ceruloplasmin is rarely useful in dystonia that emerges in older adults. In older adults, ceruloplasmin is evaluated only when there are other features that raise suspicion for Wilson disease such as coexisting liver disease or corneal Kaiser-Fleischer rings.

Other specific tests may also be warranted. Examples include blood acanthocytes (neuroacanthocytosis) or autoantibodies (autoimmune and neoplastic disorders). Cerebrospinal fluid studies are sometimes advocated to rule out neurotransmitter disorders with dystonia, such as dopa-responsive dystonia. However, cerebrospinal fluid studies are not routinely conducted for patients with dopa-responsive dystonia for a number of reasons. These include the simpler approach of levodopa challenge, the requirement for lumbar puncture, need for special preservative-containing tubes, which may not be available in the clinic, uncertain sensitivity and specificity for various subtypes of dopa-responsive dystonia, and availability of more definitive blood-based gene tests to identify most subtypes.

Genetic Testing

The many recent advances in genetic technology have led to a nearly constant evolution of diagnostic testing strategies for all inherited neurologic disorders. Different experts often recommend different testing strategies, although there are some common principles.

Genetic testing is not usually conducted when dystonia emerges in older adults (>40 y of age), unless there are affected family members. Genetic testing can also be useful in adults when additional clinical features point to a known inherited syndrome.

For dystonias that begin in younger individuals (<40 y of age), genetic testing can be guided by the recognition of specific "red flags" or a syndromic *pattern* that points to a specific disorder or group of disorders. A good example of a red flag is the corneal Kayser-Fleischer ring of Wilson disease. An example of a syndromic pattern might be Lesch-Nyhan disease where this is a combination of generalized dystonia, intellectual disability, self-injurious behavior, and elevated serum uric acid. In both of these disorders, the clinical syndrome is relatively specific for a single disorder. As a result, targeted laboratory testing may be conducted in these situations. Although red flags and characteristic syndromes are useful when they are found, they are lacking for many types of dystonia. In addition, red flags may be absent when they should be present, and atypical syndromes are common.

When the clinical picture is not helpful to narrow the scope of diagnostic tests, there has been an increasing tendency to go directly to large dystonia gene panels or clinical exome sequencing. It is important to avoid serial genetic testing, a strategy that involves predicting the most likely responsible gene and following a negative result with sequential testing until the answer is found. This strategy is more expensive than ordering a whole panel, and it is frustrating to patients and families. Similar to other early-onset neurologic disorders (eg, epilepsy, intellectual disability, ataxia), currently available gene panels or clinical exome sequencing generate a clinically useful result in about a third of all cases in studies of large undiagnosed cohorts of subjects with dystonia. If a gene panel is used, it is important to know what it includes. Different diagnostic testing labs include different numbers of genes from only a few to more than 100.

Even when a diagnostic result cannot be found, it remains important to follow patients over time. Patients may develop additional problems that make the diagnosis more obvious, or previously obtained exome results may be reinterrogated for newly discovered dystonia genes. For example, approximately 10% to 15% of patients with Parkinson disease may present with focal dystonia of an arm or leg, closely resembling a sporadic adult-onset isolated limb dystonia. However, signs of parkinsonism may develop within years or months, making the diagnosis of Parkinson disease more obvious. In younger individuals, this type of progression may suggest an inherited disorder that combines dystonia and parkinsonism.

MANAGEMENT

There are many treatment options for the dystonias. They include oral medications, botulinum toxin injections, surgical interventions, and others. Each of these options is described further in the text that follows. The broad strategy for how these options may be used for different types of dystonia is shown in Figure 79.7. This schematic provides only a general guide, and treatments must be individualized.

In recent years, there has been increasing enthusiasm for providing treatment recommendations from "evidence-based medicine." The processes for evaluating evidence for specific treatments have been standardized, and reaching the highest levels of evidence for treatment recommendations requires the availability of data from multiple large randomized and placebo-controlled clinical trials. For example, "level 1" evidence requires at least one large properly designed randomized clinical trial. The process for delineating recommendations was developed for common disorders, not rare disorders. For many reasons, multiple large clinical trials are rarely conducted for rare disorders, including the dystonias. As a result, many established treatment options for dystonia fail to reach the highest levels of evidence for their recommendation.

For example, one of the most reliably effective treatments across all subtypes of dystonia is levodopa for dopa-responsive dystonia. However, there are no large randomized clinical trials proving the efficacy of levodopa for any form of dystonia.

FIGURE 79.7 Basic algorithm for management. This algorithm provides a basic strategy for the approach to most patients with dystonia. The actual management should be done on a case-by-case basis because exceptions to this plan may occur. Management depends on the clinical diagnostic evaluation because the subtype of dystonia determines the optimal treatments strategies. Age plays a key starting role. For children, diagnostic testing is important because there are special populations with specific treatments (see **Table 79.10**). All other children should have a trial of oral levodopa to rule out dopa-responsive dystonia. The use of other oral agents or feasibility of using botulinum toxin will depend on the body distribution of dystonia. For most adults, dystonia is idiopathic, and the treatment approach depends more on body distribution. For adult-onset focal dystonias, botulinum toxins are the treatment of first choice. Oral medications may play an adjunctive role, and those who have unsatisfactory responses proceed to surgery. For adults with generalized dystonia or dystonia combined with other neurologic problems, laboratory testing may be more valuable for disclosing a treatable cause.

Therefore, this treatment does not reach criterial for level 1 evidence. In this situation, "evidence-based medicine" becomes "evidence-limited medicine," and recommendations must be made on the basis of good clinical practice. With these caveats in mind, there is level 1 evidence for the use of specific botulinum toxins for patients with cervical dystonia and blepharospasm. There also is level 1 evidence for the use of DBS for patients with generalized and segmental dystonia as well as for patients with cervical dystonia who fail botulinum toxin. A summary of treatment studies summarizing levels of evidence can be found in the suggested reading list at the end of this chapter.

Counseling

Counseling plays an important role for all patients with dystonia. Except for the rare subtypes of dystonia with specific treatments described in the preceding text, patients must be prepared for a trial and error approach to finding the best solutions. Customization of the treatment plan can take several months for oral agents, botulinum toxins, and surgery. Frustration can be avoided if patients are adequately informed in advance, and patients should be prepared, so they do not abandon treatment too early.

In addition to frustration associated with the time required to work out optimal treatments, there is a high frequency of psychiatric comorbidities for many types of dystonia. The adult-onset focal dystonias are associated with high rates of depression, anxiety, and social withdrawal. Specific psychiatric comorbidities are even more common in certain genetically determined subtypes of dystonia, such as the myoclonus-dystonia syndrome associated with *SGCE* mutations. It is important to ask about these problems and provide guidance where needed.

Oral Medications

There are no U.S. Food and Drug Administration-approved drugs specific for the treatment of any type of dystonia. Large placebo-controlled and double-blinded clinical trials are scarce. However, many drugs have been empirically found to be helpful (Table 79.10). These have been summarized in several evidence-based, or expert-consensus reviews. The most commonly used drugs are summarized in text that follows.

TABLE 79.10 Some Oral Medications for Dystonia

Medication Type	Typical Examples
Anticholinergics	Benztropine, biperiden, ethopropazine, orphenadrine, procyclidine, trihexyphenidyl
Dopaminergics	Levodopa, deutetrabenazine, tetrabenazine, valbenazine
GABAergics	Alprazolam, baclofen, chlordiazepoxide, clonazepam, diazepam
Muscle relaxers	Carisoprodol, chlorzoxazone, cyclobenzaprine, metaxalone, methocarbamol, orphenadrine
Miscellaneous	Carbamazepine, cannabidiol, cyproheptadine, gabapentin, lithium, mexiletine, nabilone, riluzole, tizanidine, zolpidem

Drugs Targeting Acetylcholine Pathways

Drugs that suppress brain acetylcholine signaling can be useful for many types of dystonia, regardless of the underlying cause. For example, anticholinergics can be helpful for inherited childhood-onset generalized dystonias as well as sporadic adult-onset focal dystonias. Although trihexyphenidyl is commonly prescribed, other anticholinergics are also effective. Despite their broad application, efficacy is limited and side effects can be problematic because unusually high doses are sometimes required.

Common side effects for adults include dry mouth or dry eyes, constipation or urinary retention, blurry vision or worsening of narrow-angle glaucoma, and depression. In older adults, memory loss and confusion are not uncommon. It is said that children tolerate high doses better than adults. However, it is important to monitor school performance because side effects may cause more subtle effects on behavior or cognition. In some children, anticholinergics may worsen abnormal movements.

Drugs Targeting Dopamine Pathways

Drugs that augment dopamine signaling can be useful for selected subtypes of dystonia. Levodopa is usually remarkably effective for children with dopa-responsive dystonia. Many children respond within a few days to small doses, for example, two tablets of 25/100 of carbidopa/levodopa daily. However, it is a common error to assume that all children respond quickly to such small doses. Higher doses and longer durations of treatment are required in approximately 10% to 20% of cases. Current recommendations call for titrating the levodopa total amount to 20 mg/kg per day split across three to four daily doses, given for at least 1 month. Levodopa also is usually effective for dystonia in juvenile-onset Parkinson disease. It may also be useful for dystonia that occasionally occurs in spinocerebellar ataxia type 3, ataxia-telangiectasia, and several other inherited dystonias. However, levodopa is not generally effective in more common adult-onset isolated focal or segmental dystonias. In view of these observations, a levodopa trial is not generally conducted for adult-onset dystonias, but it is mandatory for dystonia that begins in children and young adults.

Conversely, drugs that reduce dopamine signaling may be helpful for other types of dystonia. The reason that drugs augmenting or reducing dopamine signaling may be beneficial for different types of dystonia is not clear but probably reflects different pathologic processes underlying different types of dystonia. Drugs that deplete dopamine stores (eg, tetrabenazine, deutetrabenazine, valbenazine) may reduce symptoms in tardive dystonia. In the past, dopamine receptor antagonists were sometimes offered to patients with dystonia. This class of medications is no longer encouraged because side effects may include acute dystonic reactions or tardive dystonia. In a patient who already has dystonia, worsening symptoms can cause confusion regarding progression of the underlying condition versus superimposed side effects.

Drugs Targeting γ-Aminobutyric Acid Pathways

Drugs that amplify γ-aminobutyric acid signaling can also be useful for many types of dystonia regardless of underlying cause. The most commonly used are the benzodiazepines such as clonazepam and alprazolam. These drugs must be used with caution because they may be habit-forming, and abrupt discontinuation

can lead to withdrawal reactions. Typical side effects include drowsiness, impaired memory and concentration, imbalance, and depression.

Baclofen is most often used in childhood-onset dystonias that are combined with spasticity. High doses are often required, and typical side effect may include dizziness, altered mentation, and sometimes loss of muscle tone. When side effects become limiting, baclofen can be delivered intrathecally via implanted minipumps. Abrupt discontinuation or pump failures can cause severe withdrawal reactions that include seizures and altered mental status. Oral baclofen is sometimes also prescribed for more common adult-onset dystonias, although efficacy is limited in most cases.

Miscellaneous Drugs

Because the core problem in dystonia involves excessive muscle contractions, patients often request treatment with "muscle relaxants." This category has drugs with varied mechanisms of action such as baclofen, benzodiazepines, carisoprodol, chlorzoxazone, cyclobenzaprine, metaxalone, methocarbamol, orphenadrine, and many others. These medications can sometimes be useful for patients who have pain from muscle spasms.

The literature contains numerous anecdotal and uncontrolled reports of other drugs. They include amphetamines, cannabis-related products such as cannabidiol oil, cyproheptadine, gabapentin, lithium, mexiletine, nabilone, riluzole, tizanidine, zolpidem, zonisamide, and others. These medications are not widely used because experience is limited.

Special Populations

There are highly effective therapies for some subtypes of dystonia (Table 79.11). Although all of these treatable dystonic disorders are rare, they should not be missed because treatment can be life-altering.

For example, there are several disorders where dystonia results from the accumulation of a substance that is toxic to the nervous system. Patients with Wilson disease respond to treatments that reduce copper stores, and patients with disorders of manganese transport respond to treatments that reduce manganese. Other disorders respond to supplementation of the diet with vitamins or other supplements, such as biotin-thiamine responsive basal ganglia disease. Some disorders respond at least in part to avoidance of known triggers or specific dietary modifications.

In addition, there are several disorders that respond to specific medications targeting specific mechanisms. The best known is dopa-responsive dystonia, which responds to levodopa and other strategies that augment dopamine levels. Paroxysmal kinesigenic dyskinesia often responds to low doses of carbamazepine or related anticonvulsants. Alcohol is beneficial in the myoclonus-dystonia syndrome, but it is not usually recommended as routine therapy because of the risk for alcohol dependence.

Botulinum Neurotoxins

Injections of botulinum neurotoxins (BoNT) provide the treatment of first choice for many forms of dystonia. The use of BoNT is supported by multiple double-blind, randomized, placebo-controlled trials, and several evidence-based reviews have been published. Several BoNT formulations are available, and there are numerous articles that summarize their similarities and differences (Table 79.12). There also are numerous resources that describe their applications in various disorders. This section provides a summary of their more common uses and caveats.

Applications

For cervical dystonia, BoNT suppresses abnormal head and neck movements, reduces pain from neck muscle pulling, and improves quality of life. Improvements are typically seen 2 to 7 days following injection, and benefits last for an average of 12 weeks. The first treatment usually begins with a conservative dose, which must be titrated upward with customization of the distribution of muscles injected over 2 to 3 treatment cycles. Therefore, it is important to caution patients that this process may take several months. Good results may be achieved in the majority of patients with cervical dystonia, but some patients are more difficult to treat than others. Subtypes that are more difficult to treat include patients with predominant anterocollis, patients with prominent head tremor, and long-standing abnormal postures that may be accompanied by contractures.

For blepharospasm, BoNT suppresses excessive blinking and orbicularis oculi muscle spasms, reduces vision-related disability, and improves overall quality of life. Good results can be achieved in the majority of patients with blepharospasm. Blepharospasm patients who develop apraxia of eyelid opening are more difficult to treat, unless the palpebral muscles are injected. Patients who develop lower facial muscle spasms also are more challenging to treat because muscles around the mouth are very sensitive and there is a risk for loss of smile or facial asymmetry, drooling, slurred speech, or lip biting. Similar to cervical dystonia, benefits in blepharospasm emerge within a few days and last for an average of 12 weeks.

BoNT is also widely used for laryngeal dystonia and has been shown to reduce abnormal voice breaks and the effort associated with speaking. The abductor spasmodic dysphonia subtype is more challenging to treat than the adductor spasmodic dysphonia subtype. BoNT may also be used for other focal dystonias including oromandibular dystonia, upper or lower limb dystonias, and truncal dystonia. BoNT can be helpful for segmental and multifocal dystonia too, but feasibility becomes increasingly challenging as the number of muscle groups affected increases. Nevertheless, BoNT can be useful even in generalized dystonia, by targeting the regions that are most affected. For example, the lower limbs can be targeted in patients with generalized dystonia to alleviate pain and long-term consequences of contractures.

Contraindications and Side Effects

Contraindications to BoNT include neuromuscular disorders that cause weakness, such as myasthenia gravis, Eaton-Lambert syndrome, or motor neuron disease. The contraindications are not absolute, and these patients may benefit from BoNT with proper dose adjustments.

In experienced hands, side effects from BoNT injections are usually minor and transient. Short-term side effects depend on the region injection. For cervical dystonia, these may include dysphagia, head drop, and dry mouth. Side effects of BoNT treatment in blepharospasm may include ptosis, dry or irritated eyes, facial asymmetry, and rarely diplopia. Incomplete eyelid closure may also occur. If the eyes remain partly open while sleeping at night, corneal drying and permanent corneal scarring can occur. Transient voice hoarseness is a common side effect of BoNT treatment of laryngeal dystonias, sometimes with dysphagia.

TABLE 79.11 Treatable Inherited Dystonias

Disorder	Gene	Typical Age of Onset	Typical Clinical Features	Treatment
Abetalipoproteinemia (Bassen-Kornzweig)	*MTTP*	Childhood to early adulthood	Progressive ataxia, chorea, dystonia (often oromandibular), seizures, acanthocytosis, retinitis pigmentosa, fat malabsorption	Early treatment with vitamin E and reduced fat diet can prevent or reduce symptoms.
Aromatic amino acid decarboxylase deficiency	*AADC*	Infancy	Motor delay, hypotonia and dystonia, oculogyric crises, autonomic dysfunction	Dopamine agonists and monoamine oxidase inhibitors can partly reverse symptoms in some cases.
Ataxia with vitamin E deficiency	*TTPA*	Childhood to early adulthood	Ataxia, visual loss, neuropathy; occasional patients present instead with dystonia	Early treatment with vitamin E can prevent or reduce symptoms.
Biotin-thiamine responsive basal ganglia disorder	*SLC19A3*	Childhood	Encephalopathic crisis with generalized dystonia	Biotin and thiamine can reverse or prevent symptoms.
Biotinidase deficiency	*GTD*	Infancy	Encephalopathy, motor delay, dystonia, seizures, visual and auditory impairment, skin rash	Early treatment with biotin can prevent or reduce symptoms.
Cerebral folate deficiency	*FLR1, SLC46A1*	Early childhood to adolescence	Developmental delay, ataxia, dystonia, seizures, neuropsychiatric disturbances	Folinic acid can prevent or reduce symptoms.
Cerebrotendinous xanthomatosis	*CYP27A*	Late childhood to adulthood	Ataxia, spasticity, dementia, dystonia, myoclonus, tendon xanthomas	Chenodeoxycholic acid may prevent progression or reverse some features.
Cobalamin deficiencies (subtypes A-G)	Multiple	Infancy	Encephalopathy, motor delay, ataxia, spasticity, dystonia, seizures, bone marrow abnormalities	Cobalamin derivatives and/or protein restriction can mitigate symptoms.
Coenzyme Q10 deficiency	Multiple	Any age	Varied phenotypes of progressive ataxia or encephalopathy, sometimes with dystonia	Coenzyme Q10 can prevent or reduce symptoms.
Cerebral creatine deficiency (type 3)	*GAMT, AGAT*	Infancy	Global delay, myopathy, generalized dystonia	Creatine ± arginine restriction can mitigate symptoms.
Dopa-responsive dystonia (classic)	*GCH1*	Early childhood to late adulthood	Dystonia often combined with parkinsonism	Levodopa can reverse symptoms.
Dopa-responsive dystonia (complicated)	*TH, PTPS, SPR*	Infancy to adolescence	Dystonia often combined with parkinsonism, oculogyric crises, autonomic disturbances	Levodopa, 5-hydroxytryptophan, and/or tetrahydrobiopterin can completely or partly reverse symptoms.
Dystonia with brain manganese accumulation	*SLC30A10, SLC39A14*	Childhood	Progressive dystonia with parkinsonism, liver disease, polycythemia	Chelation therapy can prevent or at least partly reverse symptoms.
Galactosemia		Childhood to early adulthood	Ataxia, tremor, lactose intolerance, sometimes with mild dystonia	Lactose restriction can prevent or mitigate symptoms.
GLUT1 deficiency	*SLC2A1*	Childhood to adolescence	Developmental delay, seizures; sometimes paroxysmal exertional dystonia	Ketogenic diet or triheptanoin can prevent or reduce symptoms.
Glutaric aciduria (type 1)	*GCDH*	Early childhood to early adulthood	Developmental delay with encephalopathic crisis and generalized dystonia	Avoiding or treating intercurrent illness with lysine restriction can prevent encephalopathic crises.
Homocystinuria	*CBS*	Childhood	Neurocognitive dysfunction, myopia, ectopic lens; sometimes generalized or paroxysmal dystonia	Methionine restriction prevents most symptoms.
Maple syrup urine disease	*BCKDHA, BCKDHB, DBT*	Childhood	Intermittent encephalopathy with ataxia; sometimes with focal or paroxysmal dystonia	Leucine restriction ± thiamine can prevent or mitigate symptoms.
Methylmalonic aciduria	*MUT*	Childhood	Developmental delay, renal insufficiency, pancytopenia, encephalopathic crisis with generalized dystonia	Avoiding or treating intercurrent illness with protein restriction can prevent encephalopathic crises.
Molybdenum cofactor deficiency (sulfite oxidase)	*MOCS1*	Adolescence	Developmental delay, encephalopathy, seizures, rare patients present with dystonia and parkinsonism	Cyclic pyranopterin monophosphate can prevent symptoms.
Niemann Pick (type C)	*NPC1, NPC2*	Early childhood to early adulthood	Dementia, ataxia, spasticity, seizures, supranuclear gaze palsy; sometimes with progressive generalized dystonia	*N*-butyl-deoxynojirimycin (miglustat) can prevent or mitigate some symptoms.

TABLE 79.11 Treatable Inherited Dystonias *(continued)*

Disorder	Gene	Typical Age of Onset	Typical Clinical Features	Treatment
Propionic aciduria	*PCCA, PCCB*	Early childhood to adolescence	Developmental delay, encephalopathic crisis with generalized dystonia	Avoiding or treating intercurrent illness with protein restriction can prevent encephalopathic crises.
Pyruvate dehydrogenase deficiency	Multiple genes	Infancy	Progressive generalized or paroxysmal dystonia	Thiamine, ketogenic diet, dichloroacetate can mitigate symptoms.
Rapid-onset dystonia—parkinsonism	*ATP1A3*	Early childhood to late adulthood	Psychomotor delay, encephalopathic crisis with bulbar or generalized dystonia	Avoiding or treating intercurrent illness can prevent encephalopathic crises.
Wilson disease	*ATP7B*	Early childhood to late adulthood	Liver disease, Kayser-Fleischer rings, progressive dystonia, cognitive impairment, neuropsychiatric abnormalities	Zinc; tetrathiomolybdate can prevent or reduce symptoms.

Occasionally, there are systemic side effects from location injections, such as a flu-like syndrome with fatigue and myalgias.

There do not appear to be any consistent long-term side effects, even after decades of treatment. Muscle atrophy is a common side effect of BoNT treatment, but it is not permanent. Many patients may develop detectable antibodies to BoNT, although a poor correlation between antibodies and responses has questioned their clinical significance. The development of resistance to therapy from immune mechanisms is rare with current preparations of BoNT. When patients have decremental responses to therapy or appear to stop responding entirely, alternative mechanisms must be considered before concluding that they are resistant.

Surgical Treatments

There are several surgical treatment options, and these can have an enormous impact on some of the most severely affected patients with dystonia. DBS has been the most extensively studied, and there are numerous reviews describing methods, patient selection, outcomes, and side effects. Procedures that involve making focal brain lesions also remain useful for some cases. In some cases, permanent destruction of peripheral nerves or muscles can be a viable option. This section provides a brief overview of the main issues to consider when counseling or referring patients for surgical options.

Deep Brain Stimulation

DBS involves the chronic implantation of a device for low-level continuous stimulation of specific brain targets. The impulse generator is usually implanted under the clavicle or sometimes in the abdomen. It is connected to subcutaneous wires that are tunneled to specific brain targets. The most common target is the internal segment of the globus pallidus, although other targets such as the subthalamic nucleus and the thalamus are sometimes used. Chronic stimulation results in reduced dystonic movements, reduced pain, and improved quality of life.

DBS is effective for numerous types of dystonia, but not all types. As a result, a careful clinical diagnostic evaluation is critical for selecting patients most likely to respond. Dramatic improvements are reliably seen for some etiologies, such as early-onset dystonia associated with *TOR1A* or tardive dystonia acquired from neuroleptic exposure. However, DBS is ineffective for other etiologies, such as rapid-onset dystonia parkinsonism associated with *ATP1A3* and cases of cerebral palsy with imaging evidence of significant brain injury. Certain clinical features can also predict outcomes. Dynamic movements in dystonia seem to respond well, whereas tonic postures or fixed contractions may not. Isolated dystonia syndromes respond more reliably than more complex syndromes that may combine spasticity or other neurologic defects. Better responses are seen for patients with shorter disease durations, compared with those who have had dystonia for decades. Some experts believe that better outcomes are more reliably seen with younger patients, although patients of any age may respond, and those who are very young typically experience higher rates of surgical complications.

Following surgical implantation, it is important to have ready access to teams that are experienced in managing the stimulation parameters. Many patients do not experience immediate benefits, and stimulator adjustments may be required for 3 to 12 months for optimal effects. Overall, the long-term outcomes for DBS surgery are very good, with benefits lasting for many years. However, return visits should be anticipated every year to verify that the device is working optimally and assess the potential need for battery replacement.

Complications can include both acute and long-term problems. There is a small risk of acute complications related to

TABLE 79.12 Most Commonly Used Botulinum Toxins[a]

Characteristic	AbobotulinumtoxinA	IncobotulinumtoxinA	OnabotulinumtoxinA	RimabotulinumtoxinB
Preparation supplied	Freeze dried	Powder	Vacuum dried	Liquid
Dose sizes (units)	300; 500	50; 100	100; 200	2,500; 5,000; 10,000
Storage conditions	Refrigerate	Room temperature	Refrigerate	Refrigerate
Approximate dose equivalents	2.5-3.0	1.0	1.0	40

[a]As the first US Food and Drug Administration–approved botulinum neurotoxin, onabotulinumtoxinA was defined as having a strength of 1.0. The approximate dose equivalents of the other preparations are shown relative to the strength of onabotulinumtoxinA.

surgery such as infection of the surgical sites or hemorrhagic stroke relating to implantation of deep electrodes. There also is a risk of stimulation-dependent side effects if the electrodes are too close to nearby structures such as the corticospinal pathways. Long-term complications include unexpected stimulator failure, lead fracture, lead migration, and infection of the equipment. In one particularly thorough study, 47 patients with *TOR1A*-associated dystonia were followed for more than 10 years. During this period, 8.5% experienced equipment failures that required reoperation and 8.5% experienced infections of the equipment that sometimes required its removal. Another 4.3% required second operations to reposition electrodes that had migrated or were found to be in suboptimal locations following surgery.

There have been several important technological advances in DBS in recent years. These include the development batteries with longer life spans or those that can be recharged, smaller impulse generators that may be more appropriate for younger children and very thin adults, electrodes that can be controlled more precisely, and adaptation of stimulation to specific physiologic signals. Overall, DBS is a valuable therapy that can have a huge impact on certain patients with dystonia. It should be provided by multidisciplinary centers that have experience with the latest technologies, experience in selecting the right patients, and experience with managing stimulator settings and complications.

Procedures Involving Focal Ablation

Decades ago, neurosurgeons often provided focal lesions of various parts of the brain for dystonia. Outcomes were unreliable, and side effects were often permanent. After DBS became available, it rapidly became more popular, because it was reversible and adjustable. However, focal ablations have again become popular for several reasons.

First, experience has shown that small lesions of the thalamus can be reliably effective for some focal dystonias, particularly task-specific dystonias involving the hand. The complication rates are very low, and there are few long-term side effects. Second, there are circumstances where lesions may be preferable over DBS. They include particularly young or thin adults who want to avoid the cosmetic consequences of DBS, individuals who prefer to avoid the long-term requirements for lifelong management of implanted equipment, patients who may be at increased risk for infection, patients with progressive degenerative disorders requiring a palliative procedure, and individuals who live far from centers with expertise in DBS.

There also has been growing interest in focused ultrasound, which can be used to make focal brain lesions by rapid local heating of tissue. This method has been promoted as "noninvasive" because it does not carry risks associated with making an incision and passing an electrode through the brain. However, the size of the lesion made with ultrasound can be more difficult to control because it depends on many factors including target location and characteristics of the skull. The durability of the effect has also come into question, as many patients experience reemergence of symptoms after several months. Although experience is still relatively limited, this approach may become more widely available in the near future.

Procedures Involving Peripheral Nerve or Muscle

Surgically resecting peripheral nerves or muscles was routinely used for treatment of dystonia before BoNT and modern neuromodulation procedures were developed. Procedures targeting nerve or muscle are still used in certain circumstances. For example, selective peripheral denervation can be useful for cervical dystonia when BoNT fails and other surgical options are not an option. Several procedures are still occasionally offered by oculoplastic surgeons for blepharospasm when BoNT fails. These include stripping of orbicularis oculi muscles (myectomy), frontalis suspension, shortening of the levator palpebrae, and resection of excess eyelid skin. Other procedures may be offered by otolaryngologists for laryngeal dystonia. These include restructuring of the muscles or nerves and or cartilaginous structure of the larynx.

Experience with surgical strategies focusing on peripheral targets is relatively limited because they are offered only by small numbers of centers. Peripheral denervation for cervical dystonia has been the most extensively studied. In experienced hands, this procedure produces benefits that are comparable to those of DBS. Potential complications from peripheral denervation surgery in cervical dystonia include local scarring, local muscle atrophy and weakness, local sensory loss and dysesthesia, and dysphagia. Anecdotal reports describe success with oculoplastic strategies for blepharospasm and otolaryngology strategies for laryngeal dystonia, but large-scale studies summarizing efficacy and complication rates are not available.

Physical and Occupational Therapy

Many patients with dystonia request referral for additional procedures to address the discomfort associated with excessive muscle pulling. These include physiotherapy, chiropractic therapy, massage therapy, stretching exercises, acupuncture or dry needling, yoga, and others. These procedures can sometimes be useful. Some patients seem to benefit, and there are numerous unblinded reports describing benefits for various strategies. Unfortunately, the largest and most rigorous trials have failed to show any consistent benefit, and benefits are usually transient.

Although there is limited evidence-based medicine to support the use of these procedures in dystonia, they may be offered according to patient preferences. It is important to identify a therapist who has experience with dystonia because some traditional procedures may worsen dystonia or cause too much pain.

OUTCOMES

The long-term outcomes for the dystonias vary according to subtype. For the more common adult-onset focal dystonias, some worsening is expected over the first few months or years. Complete remission is uncommon, and relapse is frequent. Nevertheless, symptoms can be managed in the majority of cases with BoNT, oral medications, and sometimes surgical intervention.

For childhood-onset dystonias, progression to segmental and generalized dystonia is more frequent. Outcomes depend on the subtype. For most subtypes, symptoms can be managed with oral medications, surgical interventions, and sometimes BoNT. For certain rare subtypes, there are very specific life-altering interventions (see **Table 79.11**). As research in dystonia continues to uncover novel causes and biologic pathways, the list of dystonias with more specific interventions is likely to grow.

ACKNOWLEDGMENTS

I would like to thank Margi Patel, Laura Scorr, and Stewart Factor for providing helpful comments during development of this chapter.

Hemifacial Spasm 80

Paul Greene

KEY POINTS

1. Hemifacial spasm (HFS) produces unilateral, synchronous twitches in muscles innervated by cranial nerve VII. It can produce twitches, trains of twitches, and sustained muscle contraction.
2. Synkinesis after Bell palsy, myokymia, and less commonly tics or dystonia of the face may be misdiagnosed as HFS.
3. Epilepsia partialis continua mimics the movements of HFS but often involves the masseter muscle and the movements are rarely limited to the face.
4. Most people with HFS have something irritating the root exit zone of the facial nerve, usually an aberrantly placed artery but occasionally a tumor, an arteriovenous malformation, or other mass.
5. HFS can be treated with medications, botulinum toxin injections, or microvascular decompression surgery.

INTRODUCTION

In hemifacial spasm (HFS), there are involuntary contractions on one side of the face in muscles innervated by the facial nerve (cranial nerve VII) (Figs. 80.1 and 80.2). According to Digre and Corbett, the condition was first described in 1875 by Schultze but was first separated from other forms of facial twitching by Gowers in 1888.

EPIDEMIOLOGY

HFS is rare in United States. The age- and sex-adjusted incidence was 0.78 per 100,000 per year in Olmsted County, Minnesota, only 3% of the incidence of Bell palsy. Based on patients seeking treatment, the prevalence of HFS was 1/100,000 in Olmstead County, Minnesota (7.4/100,000 in men, 14.5/100,000 in women, and about 28/100,000 in patients between the ages of 40 and 59 years). Using similar techniques in Oslo, Norway, the prevalence of HFS was 9.8 per 100,000 (39.7/100,000 in people over 70 years).

PATHOBIOLOGY

The pathogenesis of HFS is thought to be compression of the facial nerve where it exits the brainstem (the root exit zone), usually by an aberrant artery, such as the anterior inferior cerebellar artery, posterior inferior cerebellar artery, or internal auditory artery, or a normal vein. Irritation of the nerve at this site is felt to generate spontaneous electrical activity, causing muscle contractions, and "cross-talk" or simultaneous activation of axons going to different parts of the face. However, other causes of compression at the root exit zone besides normal arteries rarely occur, such as draining veins of arteriovenous malformations, aneurysms, tumors, or plaques of multiple sclerosis in the central myelin at the root exit zone of the facial nerve. This is known as *secondary HFS*. For this reason, all patients with HFS should have magnetic resonance imaging with attention to the posterior fossa. If compression by aberrant arteries is the most common

FIGURE 80.1 The anterior inferior cerebellar artery (A) runs between cranial nerves VII and VIII and compresses nerve VII. (From Ma Z, Li M, Cao Y, Chen X. Keyhole microsurgery for trigeminal neuralgia, hemifacial spasm and glossopharyngeal neuralgia. *Eur Arch Otorhinolaryngol.* 2010;267:449-454.)

FIGURE 80.2 Muscles innervated by the facial nerve.

cause for HFS, it would be reasonable that arterial hypertension causing ectatic vessels might be a risk factor for HFS. Older studies suggested this, but recent carefully controlled studies failed to find such an association.

Occasionally, HFS has been seen after Bell palsy, bony overgrowth as in Paget disease pinching the stylomastoid foramen, and other peripheral lesions of the facial nerve. This has led to speculation that facial nerve compression induces a change in the facial nucleus, which is necessary for HFS to occur. The likelihood of such a facial nucleus change would increase as the site of compression gets closer to the nucleus. This alternative hypothesis is strengthened by the small number of cases of HFS associated with central lesions at the site of the facial nerve nucleus. In addition, there is evidence in HFS suggesting hyperexcitability of the facial nerve nucleus, including enhancement of F waves and other findings.

CLINICAL FEATURES

The contractions in HFS usually start as individual muscle twitches in the eyelids. Over time, twitches spread to other facial nerve–innervated muscles including the frontalis, paranasal muscles, zygomaticus major, perioral muscles, platysma, and occasionally, the periauricular muscles. The onset of contractions in these muscles is so close together that the twitching looks synchronous in all the muscles. Trains of twitches may develop and, when severe, there may be periods of sustained muscle contraction causing complete eye closure. Pain in HFS is very rare, usually from patients with concurrent involvement of the trigeminal nerve producing tic douloureux (the combination is called *tic convulsif*). Contractions in HFS diminish, but do not disappear, during sleep and patients often report worsening with stress. This is surprising for what is usually presumed to be a peripheral nerve disease (see the following discussion). HFS usually progresses slowly if at all but may produce facial weakness in patients with long duration of disease. About 1% of reported cases of HFS are bilateral (with twitching that is asynchronous from side to side). The majority of cases of HFS are sporadic, although there are occasional reports of familial cases (▶ Video 80.1).

DIAGNOSIS

There are few other diseases that produce twitches, trains of twitches, and occasionally, episodes of sustained muscle contraction (**Table 80.1**). Facial dystonia is usually more sustained and bilateral and muscle contractions are not usually synchronous. The rippling movements of facial myokymia are often unilateral but are slow and asynchronous. Motor tics in the face may be unilateral and rapid, but there is usually a warning sensation before the movements, and the movements are usually suppressible, at least briefly. Synkinesis after Bell palsy or other cause produces synchronous contractions but only during blinking or voluntary movement. However, some patients develop HFS in addition to a synkinesis after nerve injury. Epilepsia partialis continua does mimic the movements of HFS precisely but usually involves the masseters (cranial nerve V) and is rarely limited to the face. Spastic paretic hemifacial contracture (associated with lesions in the neighborhood of the facial nerve nucleus in the brainstem) has unilateral muscle contraction in the face but there is no twitching and there is usually myokymia.

MANAGEMENT

HFS can be treated with medications, botulinum toxin (BTX) injections, or by craniectomy and separation of an arterial loop from the root exit zone of the facial nerve (microvascular decompression).

TABLE 80.1 Differential Diagnosis of Hemifacial Spasm

Condition	Similarities to HFS	Differences from HFS
Facial dystonia	May include rapid contractions	Very rarely unilateral; mostly slower contractions; spasms not usually synchronous in different facial muscles
Myokymia	May be unilateral	Slower contractions; spasms usually asynchronous in different muscles
Motor tics	May be rapid, unilateral, and synchronous in different muscles	Usually an inner sensation before the movements; movements usually suppressible at least briefly; rarely persist during sleep
Synkinesis (eg, after Bell palsy)	May be rapid, unilateral, and synchronous in different muscles	Spasms only occur with blinking or voluntary movement.
EPC	May be rapid, unilateral, and synchronous in different muscles	Unlike HFS, may involve the masseter muscle; usually involves extracranial muscles
Spastic paretic hemifacial contracture	Unilateral contractions of facial muscles	Unlike HFS, there are no twitches. Myokymia usually accompanies the contractions.

Abbreviations: EPC, epilepsia partialis continua; HFS, hemifacial spasm.

Medication

Medications are rarely used because they are generally the least successful treatment. Medications used in the past include orphenadrine, dimethylaminoethanol, carbamazepine, clonazepam, baclofen, gabapentin, and felbamate.

Botulinum toxin injections

BTX has proved extremely useful in treating HFS, especially for orbicularis oculi contractions. Because the distribution of muscle contractions and the sensitivity to BTX varies from patient to patient, there are few specific rules for injecting the toxin. General guidelines for the injections are shown in Table 80.2.

Surgery

Microvascular decompression, first popularized by Jannetta in the 1970s, appears to be the definitive treatment for HFS. When a vessel is compressing the facial nerve, a sponge is placed between the nerve and the vessel. However, up to about 10% of patients experience return of spasms and require repeat operation, possibly when the sponge is dislodged. In addition, vascular compression of the root exit zone of the facial nerve is not found in all cases, and current magnetic resonance imaging techniques are not yet sufficient to guarantee that an offending vessel will be found. For all these reasons, many patients prefer to avoid surgery if possible, and BTX injections are the treatment of first choice for most patients.

OUTCOME

Medication

There is a single controlled study suggesting benefit from orphenadrine and dimethylaminoethanol, but this was never repeated, and this treatment is rarely used today. Successful treatment of HFS in small numbers of patients has been reported with carbamazepine, clonazepam, baclofen, gabapentin, and felbamate but improvement was "rare" in several hundred patients treated with anticonvulsants in one large series. Even when spasms improve with medications, the improvement is usually temporary.

Botulinum toxin injections

Most series describing the results of BTX injections report an almost 100% success rate, at least for spasms in the orbicularis oculi. The success rate is lower for lower facial muscles (although this is rarely reported) due to the development of facial weakness before resolution of the spasms in some patients.

TABLE 80.2 Botulinum Toxin Treatment of Hemifacial Spasm

1. Some people have dramatically different sensitivity to BTX, so initially inject just the muscle causing the most troublesome symptom (usually the Oo).
2. Optimal concentration of toxin, volume per injection, and number of sites per muscle are not known for most muscles (including the Oo). Most people use concentrations of 5-10 U/0.1 mL. The general rule is as follows: Use more dilute toxin to get a greater effect and use more concentrated toxin to get less spread to nearby muscles.
3. Major side effects are as follows:
   - Ptosis (from leakage to the levator palpebrae)
   - Ecchymoses
   - Dermatochalasis (usually in the lower lid)
   - Xerophthalmia or epiphora (usually short lasting)
   - Excess weakness of the injected muscle (not usually the Oo)
   - Diplopia (uncommon)—from lateral canthus injections
   - Entropion (rare)—from lower lid injections
4. In the Oo, avoid injecting the upper lid in the midline (to minimize the risk of ptosis). Lower lid injections are always necessary; injections in the orbital portion of the Oo are sometimes necessary.
5. Start with a small dose and increase the dose gradually to minimize side effects. Some reasonable starting doses are as follows:
   - Orbicularis oculi—2.5 units per site with one site in the lower lid, lateral canthus, medial and lateral pretarsal components of the Oo, and orbital component of the Oo
   - Frontalis—2.5 units in two or three sites
   - Nasalis—2.5 units
   - Zygomaticus major—1 unit in one site
   - Depressor anguli oris, depressor labii inferioris, mentalis—2.5 units, one site in each
   - Platysma—2.5 units in three or four sites
6. Instruct patients to always notify you about problems arising after BTX injections: Patients may coincidentally develop an unrelated problem in the weeks following a BTX injection.

Abbreviations: BTX, botulinum toxin; Oo, orbicularis oculi.

Excess weakness of the orbicularis oculi is very rare, although leakage to the levator palpebrae causing ptosis is common. The risk of ptosis depends on the volume of toxin injected (greater volume produces greater risk) and the injection site (closer to the insertion of the levator at the middle of the upper lid increases the risk). Other less common side effects include ecchymoses at the injection site, entropion of the lower lid, dry eye, excess tearing, and bagginess under the eye. Diplopia occasionally occurs, probably from spread of toxin to one or both lateral recti. All side effects from BTX injections are transient, and there is no evidence that chronic BTX injections induce any permanent change. Benefit from BTX injections for HFS lasts 3 to 6 months, after which symptoms return and repeat injections are required. Benefits from BTX injections have been so dramatic and prolonged that there has only been one small prospective, placebo-controlled crossover study and that showed significant improvement from BTX compared to placebo LEVEL 1.[1]

Surgery

In a large series describing microvascular decompression, 1,327 patients were followed for up to 3 years and 90.5% were felt to have an excellent outcome after the first surgery. There were 2.3% of patients who did not improve and had a second surgery (in the opinion of the surgeons, the wrong vessel had been decompressed), and 90% of these were felt to have an excellent response. However, up to about 10% of patients experience return of spasms and require repeat operation, possibly when the sponge is dislodged. Serious complications (death, stroke, or cerebellar hematoma) occur in less than 1% in most series. Permanent facial weakness or hearing loss is uncommon, occurring in about 5%. After surgery, delay in the onset of both facial weakness and, less often, hearing loss has been reported but the cause is not known and the deficits are usually not permanent. Other rare surgical complications including wound infection or hematoma, cerebrospinal fluid leak, bacterial meningitis, and pseudomeningocele are also possible.

Myoclonus 81

Pichet Termsarasab and Steven J. Frucht

KEY POINTS

1. Myoclonus is the fastest hyperkinetic phenomenology characterized by lightning-like jerking movements.
2. Phenomenologic characterization of myoclonus guides the anatomic localization and differential diagnoses.
3. Anatomically, myoclonus can originate from cortical, subcortical (including brainstem), spinal, or peripheral locations.
4. Myoclonus can also be etiologically classified into physiologic, essential, epileptic, and symptomatic.
5. Anatomic localization guides differential diagnoses and treatment selection.

INTRODUCTION

Myoclonus is characterized by lightning-like muscle jerks and is considered to be the fastest hyperkinetic phenomenology. Electrophysiologically, these jerks are associated with electromyographic discharges that are relatively short in duration compared to voluntary jerks. Myoclonic jerks may be positive due to active muscle contractions or negative in which jerks occur due to lapses of postural tone. The classic example of negative myoclonus is asterixis.

GENERAL CONSIDERATIONS

Epidemiology

Data on epidemiology of myoclonus are scarce. Based on a study in Olmsted County published in 1999, myoclonus has a prevalence rate of 8.6 cases per 100,000 and an annual incidence rate of 1.3 cases per 100,000 person-years. In this study, symptomatic (secondary) myoclonus was the most common (72%), followed by epileptic and essential myoclonus.

Phenomenologic Characterization of Myoclonus

When myoclonus is observed, one should attempt to answer the following questions in order to elucidate the cause:

1. What is the distribution of myoclonus? What body part(s) is(are) affected? Is it focal, segmental (affecting multiple contiguous body regions), multifocal (multiple noncontiguous body regions), or generalized?
2. Is myoclonus positive or negative (due to lapse of muscle tone) (Fig. 81.1)? The classic example of negative myoclonus is asterixis, seen in hepatic encephalopathy or uremia. Negative myoclonus of the legs when standing can be seen in patients with posthypoxic myoclonus (Lance-Adams syndrome), producing a so-called bouncing gait.
3. Is myoclonus spontaneous (occurring at rest), action induced, stimulation induced, or reflex induced? One example of stimulation-induced myoclonus is hyperekplexia, which is typically induced by somesthetic (typically in mantle area including forehead and nose), auditory, and, less commonly, visual stimuli. Reflex-induced myoclonus (a hallmark of cortical myoclonus) can be tested by using the examiner's finger to tap a body region, such as a patient's finger, hand, or arm, which then would produce a myoclonic jerk. The latency between reflex stimuli and myoclonic jerks in cortical myoclonus is relatively short, suggesting efferent conduction via the corticospinal pathway. Longer latency would suggest slower conducting pathways such as the propriospinal pathway.
4. Is the myoclonus rhythmic or nonrhythmic? Is it synchronous?
5. Are there any other associated phenomena such as dystonia or ataxia?

FIGURE 81.1 Positive and negative myoclonus. Electromyographic recordings from a patient with progressive myoclonic epilepsy during sustained muscle contraction. Positive myoclonus is seen as bursts of muscle jerks with a typical burst duration of less than 200 milliseconds. Negative myoclonus is demonstrated as a pause of electromyographic activities during sustained muscle contraction due to lapse of muscle tone. (Modified from Shibasaki H, Hallett M. Electrophysiological studies of myoclonus. *Muscle Nerve*. 2005;31:157-174.)

Myoclonus can be classified based on either anatomic localization or etiology. Anatomically, myoclonus can originate from either the central or peripheral nervous system. In the central nervous system, the location is further subdivided into cortical, subcortical including brain stem, and spinal cord origins. Anatomic classification of myoclonus is practically useful for formulation of differential diagnoses and treatment selection. The electrophysiology, etiology, and clinical characteristics of

TABLE 81.1 Classification of Myoclonus[a]

Clinical	Anatomic	Etiology

[a]Myoclonus can be classified according to clinical features, by anatomic origin of the pathophysiology of the jerks, and by etiology.

myoclonus from each anatomic location are discussed in the following text. Alternatively, myoclonus can be classified based on etiology as proposed by Marsden, Fahn, and Shibasaki as *physiologic*, *essential*, *epileptic*, and *symptomatic* (or secondary) (Table 81.1). Examples of physiologic myoclonus are jerks during sleep (hypnic jerks) and hiccups (diaphragmatic myoclonus). Symptomatic myoclonus occurs as a part of or secondary to main disorders such as storage diseases, neurodegenerative disorders, metabolic encephalopathies, etc.

After the phenomenologic characterization of myoclonus, the next step is anatomic localization, which will subsequently guide etiologic diagnosis. Here, we will classify myoclonus mainly according to anatomic localization and will integrate etiologic classification to show correlations between these two approaches.

CORTICAL MYOCLONUS

Pathobiology

The electrophysiology of myoclonus has been extensively studied. Myoclonus originating in the cortex has unique electrophysiologic features, as described in Table 81.2. The first three are unique to cortical myoclonus and are not seen in subcortical or spinal myoclonus.

Jerk-locked back-averaging technique (also known as *back-averaged electroencephalography* [EEG]) is very helpful in identifying cortical spikes prior to the jerks, but the technique is not routinely available. It is done by averaging at least 150 to 200 myoclonic jerks and capturing their preceding *cortical spikes*. A short duration between the spike and the jerk indicates fast conduction from the cortex to the muscles via the corticospinal pathway, usually less than 50 milliseconds.

Giant somatosensory-evoked potentials (SEPs) are very large cortical potentials seen by SEP recording techniques such as by stimulation of the median nerve while recording EEG. A typical SEP has negative (upward) phase followed by positive (downward) and negative phases, respectively. Only the positive and the second negative phases are enlarged in cortical myoclonus. These two latter phases are motor volleys, whereas the first negative phase is a sensory volley.

TABLE 81.2 Characteristic Electrophysiologic Features of Myoclonus From Different Anatomic Origins

Cortical Myoclonus
• Focal spikes or sharp waves of 10-40 ms duration preceding the jerk on back-averaged EEG
• Giant SEPs
• Enhanced C-reflexes
• EMG burst duration typically shorter than in subcortical or spinal myoclonus; <100 ms and usually 20-50 ms in duration
• Rostrocaudal recruitment pattern on polymyography with very fast spreading (Jerks may appear almost at the same time on regular polymyography.)
Subcortical Myoclonus Including Brainstem Myoclonus
• EMG burst durations vary among subtypes, generally longer than that seen in cortical myoclonus, as long as 100 ms.
• Typical recruitment pattern
◦ *Reticular reflex myoclonus* typically originates in the lower brainstem, most commonly CN XI–innervated muscles such as SCM. It spreads up to CNs VII– and V–innervated muscles and simultaneously down to muscles in the upper cervical levels.
◦ *Hyperekplexia* spreads between CN-innervated muscles. It can start from CN in the midbrain such as orbicularis oculi then spreading down to lower CN-innervated muscles. Jerks occur after somesthetic (touch), auditory, or, less commonly, visual stimuli.
Spinal Myoclonus
• EMG burst durations are typically longer than 100 ms.
• Spinal segmental myoclonus
◦ Recruitment pattern: Jerks start from one or two spinal segments and spread up and down along spinal segments. For example, jerking in the upper extremity from a structural lesion in the C7 spinal segment could be identified by an initial jerk of the ipsilateral triceps muscles with possible upward spreading to biceps and trapezius muscles and simultaneous downward spreading to C8-innervated intrinsic hand muscles.
◦ Velocity of spread is slower than in cortical myoclonus because it is not via fast-conducting corticospinal pathways.
• Propriospinal myoclonus
◦ Typical recruitment pattern up and down along axial muscles on polymyography. For example, jerks can originate in T12 rectus abdominis muscles and spread up and down to axial muscles above and below, respectively (eg, up to higher level rectus abdominis and down to iliopsoas).
◦ Slow velocity of spread as it is conducted through the slow propriospinal fibers (slowest among all forms of myoclonus described above).

Abbreviations: CN, cranial nerve; EEG, electroencephalography; EMG, electromyography; SCM, sternocleidomastoid muscles; SEP, somatosensory-evoked potential.

The *C-reflex* is a form of a long-latency reflex. When muscle fibers are stimulated, the afferent pathway is conducted through Ia sensory fibers, spinal cord, nucleus cuneatus or gracilis, and ultimately to the primary somatosensory cortex. Then, the efferent pathway is conducted through the corticospinal tract to the alpha-motoneuron. This typically takes about 40 to 50 seconds in the upper extremities. Therefore, when a muscle is electrically stimulated, the C-reflex will be seen on electromyography (EMG) recording about 40 to 50 milliseconds after the stimulation. C-reflexes are typically enhanced in cortical myoclonus.

Multichannel EMG recording, also called *polymyography*, can also be helpful in visualization of patterns of spread from one muscle to another, called the *recruitment pattern*. Typical recruitment patterns in cortical myoclonus are described in Table 81.2.

Clinical Manifestations

Cortical myoclonus can be focal, multifocal, or generalized. Focal cortical myoclonus usually affects the distal limbs such as the hands and fingers. It can be positive or negative, may occur either at rest or with action, and is often stimulus sensitive. It can be continuous and rhythmic, for example, *epilepsia partialis continua* in which patients have myoclonic jerks on one side of the body (▶ Video 81.1). Cortical myoclonus may occur as a fragment of epilepsy (epileptic myoclonus, see "Diagnosis" section). Posthypoxic myoclonus is typically generalized, nonrhythmic, synchronous, and stimulus sensitive (to tactile or auditory stimuli) but can also occur at rest (▶ Video 81.2).

Familial cortical myoclonic tremor with epilepsy (also called *benign adult familial myoclonic epilepsy* or *cortical tremor*) is a rare autosomal dominant genetic condition, characterized by small-amplitude myoclonic jerks in distal limbs that may look like and be misdiagnosed as essential tremor. There is a genetic heterogeneity in familial cortical myoclonic tremor with epilepsy. Several genes and loci have been identified.

Diagnosis

Cortical myoclonus can be epileptic or symptomatic, according to Marsden, Fahn, and Shibasaki's classification (see the preceding text). *Epileptic myoclonus* is fragments of epilepsy or myoclonic epilepsy and is cortical in origin. *Epilepsia partialis continua* can occur from a focal structural lesion typically seen in *Rasmussen encephalitis*, an autoimmune disorder leading to gliosis and hemiatrophy of one cerebral hemisphere (see ▶ Video 81.1).

The differential diagnosis of progressive myoclonic epilepsy is described in Table 81.3. An EEG is helpful in identifying epileptiform discharges. Investigations to confirm the diagnosis depend on the specific etiology, for example, a skin biopsy to search for Lafora bodies in Lafora body disease, or a muscle biopsy to look for ragged red fibers in myoclonic epilepsy with ragged red fibers. Genetic testing with appropriate genetic counseling is also used to confirm these entities.

Cortical myoclonus may be symptomatic, secondary to systemic or heredodegenerative disorders, for example, storage diseases or mitochondrial disorders mentioned previously. On the other hand, symptomatic myoclonus may be either cortical, brainstem, spinal, or peripheral in origin. The list of symptomatic myoclonus disorders is lengthy, and further workup depends on the suspected location and etiology. Patients with *posthypoxic myoclonus* have a history of mainly respiratory rather

TABLE 81.3 Differential Diagnosis of Myoclonus Classified by Anatomic Localization[a]

Cortical Myoclonus
• Epileptic
• Epilepsy partialis continua: Etiology can be Rasmussen encephalitis or focal cortical lesion.
• Progressive myoclonic epilepsy
• Unverricht-Lundborg disease (Baltic myoclonus, *EPM1* mutations, encoding for cystatin B)
• Lafora body disease (autosomal recessive, *EPM2A* mutations, encoding for laforin or *EPM2B* [*NHLRC1*] mutations)
• Neuronal ceroid lipofuscinosis (Batten disease, multiple mutations)
• Sialidosis (*NEU1* mutations encoding for neuraminidase)
• Myoclonic epilepsy with ragged red fibers (mitochondrial disorder)
• Dentatorubral-pallidoluysian atrophy (DRPLA, CAG repeat expansions in the *ATN1* gene encoding for atrophin)
• Symptomatic
• Posthypoxic myoclonus
• Secondary to systemic diseases or metabolic causes
• Renal or hepatic failure
• Infection related
• Subacute sclerosing panencephalitis, Creutzfeldt-Jakob disease
• Myoclonus associated with neurodegenerative disorders
• DRPLA, corticobasal syndrome, and Alzheimer disease
• Heredodegenerative disorders
• Storage diseases
• Mitochondrial disorders
• Spinocerebellar ataxia (SCA), such as SCA14

Subcortical Myoclonus Including Brainstem Myoclonus
• Subcortical
• Myoclonus-dystonia syndrome (essential myoclonus)
• Brainstem
• Physiologic
• Hypnic jerks
• Hiccups
• Hyperekplexia
• Variants include progressive encephalomyelitis, rigidity and myoclonus, and excessive startle syndromes.
• Palatal myoclonus
• Essential palatal myoclonus
• Symptomatic palatal myoclonus
• Opsoclonus-myoclonus (brainstem and cerebellum)
• Symptomatic: secondary to structural lesions in brainstem
Spinal Myoclonus
• Spinal segmental myoclonus
• Symptomatic: secondary to structural lesions in spinal cord
• Propriospinal myoclonus
Peripheral Myoclonus
• Hemifacial spasm
• Symptomatic
• Secondary to nerve root, plexus, or peripheral nerve lesions

[a]This table lists the differential diagnoses of myoclonus, primarily classified by anatomic locations. We also integrate the original etiologic classification of Marsden, Fahn, and Shibasaki, with the anatomic locations. Note that the list of symptomatic cortical myoclonus is extensive, and we include only examples. Symptomatic myoclonus (such as myoclonus from focal structural lesion) can occur anywhere within the neuraxis.

than cardiac arrest. Anoxic brain damage can be seen on neuroimaging. *Subacute sclerosing panencephalitis* is another example of symptomatic cortical myoclonus. The EEG typically reveals generalized periodic discharges every 4 to 14 seconds. *Dentatorubral-pallidoluysian atrophy* or Haw River syndrome, an autosomal dominant disorder of CAG repeat expansions in the *ATN1* gene encoding for atrophin protein, is another example in which patients can have cortical myoclonus associated with chorea, ataxia, dementia, and epilepsy. It was originally described in Japanese populations but is also found in other ethnic groups. The differential diagnoses of myoclonus associated with dementia also include *Creutzfeldt-Jakob disease*, *corticobasal syndrome*, and *Alzheimer disease*, among others. Myoclonus can also be seen in *spinocerebellar ataxia type 14*.

SUBCORTICAL INCLUDING BRAINSTEM MYOCLONUS

Pathobiology

Subcortical myoclonus originates from subcortical regions such as globus pallidus, thalamus, or brainstem. *Myoclonus-dystonia syndrome*, previously called *essential myoclonus* (also known as *DYT11 dystonia*), is thought to have a subcortical origin, given a lack of electrophysiologic features of cortical myoclonus described in the preceding text, but the exact location remains unknown. Another example of subcortical myoclonus is myoclonus occurring after thalamic stroke (typically negative myoclonus or asterixis affecting one arm). The three main types of brainstem myoclonus are reticular reflex myoclonus, hyperekplexia, and palatal myoclonus. The electrophysiologic findings are described in **Table 81.2**.

Reticular reflex myoclonus has a typical origin and recruitment pattern as described in **Table 81.2**.

Hyperekplexia, or exaggerated startle, has the nucleus gigantocellularis as a generator. It shows recruitment patterns, as described in **Table 81.2**. Lack of habituation is a feature of hyperekplexia: In the normal startle response, jerks will be less frequent and less severe clinically and electrophysiologically after repetitive stimuli, but in hyperekplexia, jerks fail to habituate.

Palatal myoclonus is another form of brainstem myoclonus, with rhythmic jerky movements of the soft palate at the rate of 2 to 2.5 Hz. Some may debate to use the term *palatal tremor*, given its regularity, but it is electrophysiologically myoclonus.

Clinical Manifestations

In *myoclonus-dystonia syndrome* (▶ **Video 81.3**), patients typically have myoclonic jerks mixed with dystonia, in the same or adjacent body regions. Myoclonus usually involves the neck and upper body such as the shoulders, arms, or hands. Dystonia seen in this condition also has similar involvement in the upper body such as the neck or hands (eg, patients can present with writer's cramp) but is usually much less prominent than the myoclonic component.

Hyperekplexia typically does not occur at rest, induced instead by a typical stimulus (▶ **Video 81.4**). Patients typically do not habituate to repeated stimuli. Nevertheless, we do not recommend examining patients with hyperekplexia with repetitive stimuli because repeated nose taps can lead to severe body stiffness and respiratory depression especially in infants.

In *reticular reflex myoclonus*, patients usually have myoclonic jerks involving the sternocleidomastoid and facial and neck muscles with the pattern of spread correlating with electrophysiologic recruitment, usually rostral and caudal.

The clinical features of *palatal* myoclonus are described in the following text.

Diagnosis

Myoclonus-dystonia syndrome is caused by a mutation in the *SGCE* gene (ε-sarcoglycan gene). This gene normally has maternal imprinting, that is, even in a normal state, maternal allele does not express. Thus, the abnormal gene is typically inherited from the father. In one rare condition, Russell-Silver syndrome where there is uniparental disomy, both alleles are from the mother, and therefore, both copies of the normal *SGCE* gene are imprinted leading to a lack of expression of one normal allele. This can cause the phenotype of myoclonus-dystonia syndrome. Symptoms of myoclonus-dystonia syndrome are usually relieved by alcohol and associated neuropsychiatric features such as anxiety and obsessive-compulsive disorder are common. Myoclonus-dystonia syndrome has also been reported to be due to other genes such as *KCTD17*.

Hyperekplexia may be hereditary or secondary. The genetics of hyperekplexia is complex: There are autosomal dominant and recessive forms. One of the well-known hereditary forms is autosomal dominant, caused by mutations in the glycine receptor gene, but other genes have also been reported. Secondary (ie, symptomatic) hyperekplexia has been reported due to brainstem encephalitis from an autoimmune or paraneoplastic process. Sometimes, it can be associated with severe muscle rigidity and stiffness, also called *progressive encephalomyelitis with rigidity and myoclonus*.

Certain excessive startle syndromes may be culturally related and also can manifest as echolalia and automatic obedience. These syndromes are known by colorful regional names, such as *The Jumping Frenchmen of Maine* (Quebec), *myriachit* (Siberia), *Latah* (Indonesia, Malaysia), and *Ragin' Cajun* (Louisiana). These syndromes are not true forms of myoclonus because the movements are more prolonged in duration and subject to conscious suppression.

Palatal myoclonus can be further classified into two forms: essential and symptomatic. In essential palatal myoclonus, patients have ear clicks from contraction of the tensor veli palatini leading to movements of the opening of the eustachian tube. Symptomatic palatal myoclonus (SPM) is a delayed phenomenon that usually occurs weeks or months after a lesion in Guillain-Mollaret triangle, which is defined by the line between dentate nucleus, contralateral red nucleus, and contralateral inferior olivary nucleus (**Fig. 81.2**). The central tegmental tract runs between red nucleus and inferior olivary nucleus, which then sends fibers to contralateral dentate nucleus through the inferior cerebellar peduncle. Then, the dentate nucleus sends a projection to the red nucleus via the superior cerebellar peduncle. Lesions in this triangle may be ischemic, demyelinating, infectious, or postinfectious, among others. Hypertrophy and hyperintensity of the inferior olivary nucleus on T2 image on magnetic resonance imaging (MRI) can be seen in SPM. Unlike essential palatal myoclonus, patients do not usually have ear clicks. Pendular nystagmus can also be seen in SPM. *Progressive ataxia with palatal tremor* is a syndrome that when seen suggests the possibility of adult-onset Alexander disease, a disorder caused by *GFAP* gene mutations. Sagittal view of the MRI in adult-onset Alexander disease can reveal atrophy of the spinal cord from the cervical portion down, giving the so-called tadpole sign. Diagnosis is confirmed by genetic testing.

FIGURE 81.2 Guillain-Mollaret triangle. Red nucleus, inferior olivary nucleus, and dentate nucleus on contralateral sides form the three corners of this triangle. The central tegmental tract runs from the red nucleus to the inferior olivary nucleus, which sends the projection to the dentate nucleus via the inferior cerebellar peduncle. Dentate nucleus sends the projection through the red nucleus via superior cerebellar peduncle. Lesions in this triangle can lead to palatal myoclonus. (Courtesy of Thananan Thammongkolchai, MD.)

In addition to the classic subcortical myoclonus mentioned in the preceding text, here we will also mention opsoclonus-myoclonus, which is due to dysfunction of brainstem and cerebellum.

Opsoclonus-myoclonus-ataxia syndrome (*Kinsbourne disease*) is diagnosed by a constellation of opsoclonus, myoclonus, and ataxia. In children, it can occur as a paraneoplastic process, typically seen with neuroblastoma associated with anti-Ri antibody, and abdominal imaging is required to screen for this cancer. In adults, it is associated with postinfectious (such as postviral), autoimmune, or paraneoplastic processes affecting the brainstem. Neuroimaging, cerebrospinal fluid studies including paraneoplastic panel in blood and cerebrospinal fluid are helpful in diagnosis. A course of steroids and/or intravenous immunoglobulin is warranted.

SPINAL MYOCLONUS

Pathobiology

Two major forms of spinal myoclonus exist: spinal segmental and propriospinal myoclonus. The typical recruitment pattern and the velocity of spread are described in Table 81.2.

Spinal segmental myoclonus typically originates within a few or several adjacent spinal segments, typically cervical or lumbar.

Propriospinal myoclonus refers to axial jerks that originate in spinal cord segments, with spread up and down along the longitudinal axis of spinal cord. The very slow–conducting propriospinal pathway helps coordinate forelimb and hind limb movements in animals, such as cats, but the role of this pathway in humans is unclear.

It has been reported in the literature that the Bereitschaftspotentials are associated with propriospinal myoclonus. The Bereitschaftspotential is a form of voluntary, movement-related potential seen on back-averaged EEG technique. It is also called a *premovement* or *readiness potential*. It is helpful in differentiating organic from psychogenic myoclonus. Thus, a psychogenic cause has been proposed in propriospinal myoclonus. However, there is evidence that there is disruption of fiber tracts in spinal cord seen on diffusion tensor imaging in patients with propriospinal myoclonus, suggesting that some forms of propriospinal myoclonus are organic.

Clinical Manifestations

In *spinal segmental myoclonus*, muscles in one or two adjacent spinal segments are typically affected. It can occur at rest or with action, may be rhythmic or nonrhythmic, but is usually not reflex induced. When patients present with myoclonic jerks in one limb, one should always think about possible pathology in the spinal cord, such as a primary spinal cord malignancy.

Propriospinal myoclonus typically presents with axial jerks (▷ Video 81.5). Patients typically have truncal flexion, usually nonrhythmic, at rest or with action or reflex induced, with a relatively long latency due to slow conduction via propriospinal pathways. The differential diagnosis of axial jerks includes propriospinal myoclonus and reticular reflex myoclonus, but in the latter form, it usually involves a higher truncal region than propriospinal myoclonus.

Diagnosis

Spinal segmental myoclonus is symptomatic until proven otherwise; therefore, neuroimaging of the spine at appropriate levels is needed. In *propriospinal myoclonus*, despite the controversies about its psychogenic versus organic origin, we also suggest obtaining neuroimaging of the spine to rule out a structural lesion.

PERIPHERAL MYOCLONUS

Pathobiology

A typical example of peripheral myoclonus is hemifacial spasm, but peripheral myoclonus can also occur from irritation of spinal nerve roots, plexus, or peripheral nerves. The EMG burst duration varies, and there is lack of electrophysiologic patterns of cortical, subcortical, and spinal myoclonus.

Clinical Manifestations

Peripheral myoclonus from nerve root, plexus, or peripheral nerve involvement typically affects a limb in the distribution corresponding to neural structures that are innervated. It usually occurs at rest and does change with action. Sometimes, it is difficult to differentiate from spinal segmental myoclonus, and spine imaging is required to rule out spinal pathology. *Hemifacial spasm* is a form of peripheral myoclonus. It is characterized by clonic, sometimes tonic, contraction of cranial nerve VII–innervated muscles, most commonly the orbicularis oculi, zygomaticus, frontalis, and platysma.

Diagnosis

Peripheral myoclonus of the limbs requires workup such as nerve conduction studies and EMG to confirm the location of the lesions, that is, neural structure involved or myotomal level. In hemifacial spasm, an MRI with visualization of the facial nerve and nearby vascular structures should be obtained. Sometimes, a vascular loop can be seen abutting the facial nerve.

MANAGEMENT

Specific treatment of myoclonus depends on the etiologic diagnosis, for example, treatment of hepatic encephalopathy when it presents with asterixis or employing antiepileptic agents in myoclonic epilepsy. Symptomatic treatment can be pursued to control symptoms along with specific treatment or when specific treatment is not available. Pharmacologic treatments commonly employed are clonazepam, levetiracetam, and valproic acid. There are no clear guidelines regarding which medication should be initiated, although anatomic localization guides treatment. The treatment is shown in Table 81.4.

TABLE 81.4 Treatment of Myoclonus[a]

Specific Treatment Depending on the Etiologies
• **Pharmacologic treatment**
• Levetiracetam (considered first-line in cortical myoclonus); 1,000-3,000 mg/d divided twice a day; dose up to 4,000 mg/d has been used.
• Two other drugs related to levetiracetam, piracetam (1,600-4,800 mg/d) and brivaracetam (50-200 mg/d; twice-daily dosing), may also be considered. Piracetam is not available in the United States. Brivaracetam failed to show efficacy as an adjunctive therapy for action myoclonus in Unverricht-Lundborg disease.
• Clonazepam (considered first-line in subcortical and spinal myoclonus); starting dose 0.5-1 mg/d; typical dose 3 mg/d or more; sometimes up to 15 mg/d
• Valproic acid; typical dose 1,000-1,500 mg/d
• Zonisamide, primidone, and perampanel (used less commonly when the aforementioned conventional medications fail); dosing for zonisamide 100-200 mg/d; for primidone, 500-750 mg/d but usually poorly tolerated at such high doses; for perampanel 2-12 mg/d
• Others (nonconventional treatments)
• Sodium oxybate in some forms of myoclonus that responds to alcohol such as myoclonus-dystonia syndrome and posthypoxic myoclonus; average dose 6.5 mg/d, maximum 9 mg/d
• 5-Hydroxytryptophan in posthypoxic myoclonus
• **Botulinum toxin injection**
• Hemifacial spasm (treatment of choice)
• **DBS**
• Pallidal DBS has been reported to improve both dystonia and myoclonus in myoclonus-dystonia syndrome, compared to VIM DBS, which improves only myoclonus but not dystonia. Data remains limited.
• Pallidal DBS has also been reported to be beneficial in posthypoxic myoclonus.

Abbreviations: DBS, deep brain stimulation; VIM, ventral intermediate nucleus.
[a]Specific treatment of myoclonus depends on the etiologic diagnosis. Symptomatic treatment can be considered along with specific treatment or when specific treatment is not available.

OUTCOME

The prognosis and natural history of myoclonus depend on its specific etiology. For example, prognosis is generally good after treating an underlying systemic disorder, removing a structural lesion, or treating an underlying autoimmune or paraneoplastic process. The outcome of other forms of myoclonus is variable.

Hereditary and Acquired Ataxias 82

Sheng-Han Kuo and Vikram G. Shakkottai

KEY POINT

1. Cerebellar ataxia may result from a heterogeneous group of conditions, including nutritional, immune, inherited and degenerative etiologies.
2. Identification of nutritional and immune-mediated ataxias is important as these are treatable entities.
3. A tiered approach to genetic testing is the most cost-effective way to make a diagnosis of inherited ataxia. Start with testing for repeat-expansion associated ataxia, and if negative consider whole-exome sequencing.
4. In addition to symptomatic pharmacological therapy, intensive coordinative training can provide benefit for ataxia symptoms.

INTRODUCTION

The cerebellum controls the coordination of human movement, and the dysfunction of the cerebellum and its efferent or afferent connections leads to incoordination, which is termed *ataxia*. The diversity in the causes of cerebellar ataxia can pose significant diagnostic challenges; the treatment options for cerebellar ataxias have been traditionally thought to be ineffective, leaving many patients with ataxia untreated. In addition, the nonmotor symptoms, such as depression and mood disorders, are just beginning to be understood as part of the clinical presentation in ataxic disorders. Many emerging therapies for ataxia are on the horizon, accelerated by the advancement of scientific understanding of the neuroanatomy and neurophysiology of the cerebellum in both the normal state as well as in the disease. Therefore, cerebellar ataxia has been at the forefront of neurologic discoveries and novel therapy development.

This chapter starts with a brief introduction of cerebellar anatomy and physiology and details the clinical symptoms and signs commonly seen in ataxia patients. A discussion on the diagnostic modalities, including laboratory, neuroimaging, and genetics tests follows. An algorithm to pinpoint the etiology is outlined. Although an entire chapter can be devoted to each cause of cerebellar ataxia, a comprehensive overview of each ataxia diagnosis is provided. Finally, therapy under development for cerebellar ataxia is highlighted, a source of hope for patients. Recent developments in ataxia therapeutics make this an area of considerable promise in clinical neurology.

Neuroanatomy of the Cerebellum

The neural circuitry of the cerebellum is very distinctly organized with defined affect and efferent connections with other brain regions (Fig. 82.1). Disturbance of these brain structures leads to cerebellar ataxia. The cerebellum receives various sensory afferent inputs, such as vestibular and proprioceptive input. Another important input to the cerebellum is from the cortex through corticopontocerebellar fibers. All these inputs become mossy fibers that project to the cerebellar cortex, where they form synapses with granule cells whose axons become parallel fibers. In addition to mossy fibers, axons of the neurons in the inferior olivary nucleus provide another important afferent to the cerebellar cortex, known as *climbing fibers*. Purkinje cells, the principal neurons of the cerebellar cortex, receive two excitatory synaptic inputs; one from parallel fibers and the other from climbing fibers. Parallel fibers form synapses with thin, distal parts of Purkinje cell dendrites, whereas climbing fibers form synapses with proximal parts

FIGURE 82.1 Neuroanatomy of the cerebellum.

of Purkinje cell dendritic shafts. The proper climbing fiber and parallel fiber wiring on Purkinje cells is critical for normal cerebellar function. Other inhibitory interneurons, such as Golgi and basket cells, are also important to shape Purkinje cell firing. Purkinje cells are the sole output neurons in the cerebellar cortex and Purkinje cell axons project to deep cerebellar nuclei (dentate nucleus, interposed nucleus, and fastigial nucleus), which send axonal projections to the thalamus and subsequently to motor cortex and other associated brain regions.

The anterior lobe of the cerebellum is important for motor control, whereas, the majority of the posterior lobe of the cerebellum may be related to cognitive processing. Within the motor cerebellum, lesions in the midline structure often result in truncal or gait ataxia, whereas damage to the paravermal regions is more likely to result in appendicular ataxia. Understanding the relationship between cerebellar neuroanatomy and cerebellar behavioral function can help with lesion localization.

CEREBELLAR NEUROPHYSIOLOGY

Cerebellar Circuits

Cerebellar Purkinje cells and nuclear neurons are autonomously active with high baseline firing rates. Purkinje cell projections, the major input to the neurons of the cerebellar nuclei, are inhibitory. Input into the cerebellum is predominantly through excitatory mossy fibers, which excite Purkinje cells through granule cells. Mossy fiber collaterals also directly excite cerebellar nuclear neurons. Bidirectional modulation of Purkinje cell firing frequency is possible through excitation mediated by parallel fiber synapses and inhibition mediated by cerebellar cortical interneurons, such as stellate cells or basket cells. One set of Purkinje cells can be excited with simultaneous inhibition of flanking sagittally oriented Purkinje cells by a distinct patch of granule cells. Distinct Purkinje cells are presumed to receive excitatory input representing distinct agonist muscle groups and inhibitory input from antagonist muscles. Similarly, cerebellar nuclear neurons receive input from distinct groups of Purkinje cells, whose inhibitory input would be expected to reduce their firing frequency. Bidirectional modulation of cerebellar nuclear neuron firing frequency would be expected through release of inhibition (and stimulation through mossy fiber collaterals) and increased inhibition through Purkinje cells. Another important modulator for Purkinje cell firing is by climbing fibers. Climbing fibers are axons of inferior olivary neurons, and a Purkinje cell only receive synaptic connections with one climbing fiber in the mature cerebellum. Climbing fibers can modulate Purkinje cell synchrony, which will result in strong modulatory effect in the downstream cerebellar nuclear neurons.

Control of Movement by the Cerebellum

Recordings from nonhuman primates performing simple movements, demonstrate characteristic patterns of activity in Purkinje cells and cerebellar nuclear cells. Simple spikes of most Purkinje cells occur at high maintained frequencies of about 70 Hz at rest. During flexion and extension movements at the wrist, Purkinje cell simple spike frequency alternates between rates higher (up to 400-500 Hz) and lower than the resting rate with a consistent temporal relationship to each successive movement cycle. Purkinje cells and cerebellar nuclear neurons change firing frequency in relation to whether muscles are active during a motor task. Distinct Purkinje cells (and downstream nuclear neurons) are likely involved in the timing of muscle activity. Because the majority of cerebellar nuclear neurons are excitatory, it suggests that an increase in firing of cerebellar nuclear neurons corresponds temporally with facilitation of muscle activity, and a decrease in firing frequency reduces facilitation of muscle groups. Although the firing of some Purkinje cells correlates positively with muscle activation, it is unclear how these data may be integrated into models of cerebellar control of limb movement. Only a subset of cerebellar output neurons are presumed to directly regulate motor activity of the limb, with others that discharge in relation to joint position, and the direction of the intended next movement. Although some investigators favor the view that the cerebellum solely plans and controls movements in a kinematic framework, without directly encoding force-related parameters, at least a subset of cerebellar output neurons do appear to directly activate muscle groups as evidenced by electrical stimulation of interposed and dentate nuclei in primates. Also, optogenetic manipulation of Purkinje cells in mice shows that inhibiting Purkinje cell firing can cause muscle contraction. In addition to real-time control of movement by the cerebellum, activity of cerebellar neurons can be modified by plasticity at various sites in the cerebellar circuit. Long-term depression of synaptic activity at parallel fiber synapses, is a particularly well-studied and important learning mechanism in the cerebellum. Additionally, an interaction between the cerebellar and basal ganglia motor control systems may allow cerebellar output neurons to influence muscle activity.

EPIDEMIOLOGY

The prevalence of ataxia is estimated to be 25 to 30 cases per 100,000 in the United States; however, this estimate mostly comes from referral centers, and there are few population-based studies. Nongenetic ataxia outnumbers genetic ataxia in most studies. Among the autosomal dominant ataxias or spinocerebellar ataxias (SCAs), SCA3 is the most common, followed by SCA2, SCA6, and SCA1. Friedreich ataxia is the most common autosomal recessive ataxia. The prevalence of genetic forms of ataxia varies in different geographic regions and ethnic backgrounds. Even with a family history of ataxia, approximately 30% of patients have no known genetic mutations identified. The prevalence of undiagnosed inherited forms of ataxia is expected to decrease due to advances in genetic technologies.

CLINICAL APPROACH TO CEREBELLAR ATAXIA

Signs and Symptoms of Ataxia

The first step to approach ataxia patients is to recognize early symptoms (Table 82.1). Difficulty walking and imbalance are often the first symptoms in ataxia patients. In the early stages of ataxia, patients may experience difficulty going upstairs and downstairs, and report having to hold onto the railing. Other early symptoms in gait ataxia include difficulty in running, walking in high heels, walking barefoot on the beach, and veering toward one side. A commonly used question to probe early symptoms of ataxia is "do you walk as if you are drunk?" Along this line, some patients will exhibit sensitivity to a small amount of ethanol. Patients with more severe ataxia often fall frequently.

TABLE 82.1 Signs and Symptoms for Cerebellar Ataxia

Early Signs and Symptoms
Difficulty in running, jumping, walking, or turning
Difficulty in walking on high heels
Difficulty in walking upstairs and downstairs without holding on to the railings
Sensitive to alcohol—balance become worse after a small amount of alcohol
Slurred speech—occasionally difficult to be understood; could be intermittent in early stage
Clumsiness in handwriting
Dizziness
Double vision—particularly when turning head quickly
Incidental finding of cerebellar atrophy on neuroimaging studies
Hand tremor
Late Signs and Symptoms
Falls
Difficulty in balance
Walking as if drunk
Swallowing difficulty
Blurry vision
Clumsiness in hands—difficulty in dressing and using utensils

Other than gait, visual problems can also occur. In the early stages of ataxia, patients may experience double vision when turning their heads quickly. As a result of transient and mild double vision, some may have blurry vision. Slurred speech is often not the initial symptom but can develop with disease progression. Patients can also have loss of hand dexterity with impaired handwriting and difficulty in performing delicate hand tasks.

It is very important to determine the timing of the development of ataxia (acute vs subacute vs chronic vs episodic), which has important diagnostic implications. Table 82.2 lists the common causes for ataxia with different chronicity. Toxic, metabolic, infectious, and vascular etiologies often develop quickly, whereas immune-mediated ataxias have subacute onset courses. Degenerative and genetic ataxias usually progress relatively slowly.

Besides recognizing ataxia symptoms, other associated symptoms can often point toward the diagnosis and thus are an important part of the history. These symptoms include peripheral neuropathy, parkinsonism, sleep dysfunction, autonomic symptoms, seizures, hearing loss, and a family history for ataxia and other balance problems. History of toxin and medication exposure, such as antiepileptic medications and chemotherapy, could also be the key to identifying the etiology of ataxia.

It is also very important to consider ataxia mimics, such as sensory neuropathy, parkinsonism, normal pressure hydrocephalus, vestibular problems, spasticity, muscle weakness, orthopedic issues, and pain-related gait disturbance (Table 82.3).

Neurologic Examination

The cerebellum is important for coordination and motor control throughout the body; therefore, cerebellar ataxia can be divided into several domains: eyes, speech, hands, legs, and gait, which should be the main focus on the neurologic examination.

TABLE 82.2 Acute, Subacute, Chronic, and Episodic Causes of Cerebellar Ataxia

Acute Causes of Cerebellar Ataxia (Minutes to Few Days)
Vascular causes: ischemic or hemorrhagic cerebellar strokes
Alcohol intoxication
Toxin (mercury, thallium, toluene, solvents)
Medication induced (phenytoin, carbamazepine, phenobarbital, lithium)
Demyelinating diseases, including multiple sclerosis
Meningitis, particularly basilar meningitis
Viral cerebellitis
Cerebellar abscess
Wernicke encephalopathy/thiamine deficiency
Subacute Causes of Cerebellar Ataxia (Weeks to Months)
Paraneoplastic cerebellar degeneration
Brain tumors
Creutzfeldt-Jakob disease
Superficial siderosis
Anti-GAD ataxia
Tuberculosis meningitis
Sarcoidosis
Chronic Causes of Cerebellar Ataxia (Months to Years)
Ataxia associated with gluten sensitivity
Genetic ataxia
Mitochondrial disease
Multiple system atrophy
Idiopathic late-onset cerebellar ataxia
Episodic Causes of Cerebellar Ataxia
Genetic episodic ataxia
Psychogenic ataxia
Mitochondrial disease
Multiple sclerosis

TABLE 82.3 Differential Diagnosis and Conditions That Can Mimic Cerebellar Ataxia

Sensory neuropathy/neuronopathy
Parkinsonism
Magnetic gait/normal pressure hydrocephalus
Vestibular problems
Upper motor neuron symptoms/spasticity
Muscle weakness
Orthopedic issues
Pain-related gait disturbance
Psychogenic movement disorders

The classical motor examination of ataxia can be divided into eight different categories, as outlined by the Scale for Assessment and Rating of Ataxia, a validated measure of ataxia severity. This scale has been extensively used by ataxia specialists to track ataxia progression. However, this scale does not assess eye movement abnormalities in ataxia. Video 82.1 demonstrates a complete Scale for Assessment and Rating of Ataxia examination.

Cerebellar dysarthria is often described as "scanning speech," which refers to words broken up into individual syllables. The speed of speech is slow, possibly to compensate for slurred speech, and the volume of speech is variable, which is the core feature of cerebellar dysfunction. To test for hand dexterity in ataxia, three tasks are commonly used: (1) finger-nose testing (the patient points repeatedly with his index finger from his or her nose to examiner's finger), (2) finger chase (the patient's index finger follow examiner's moving index finger as precisely as possible), and (3) fast alternating movements (the patient performs cycles of repetitive alternation of pronation and supination of the hand on his or her thigh). Patients with cerebellar ataxia overshoot on the finger chase exam and demonstrate intention tremor on finger-nose testing. During fast alternating movements, ataxic patients have irregular movements and often make errors of timing. To assess for lower extremity cerebellar function, patients are asked to perform the knee-shin-slide (the patient straightens one leg and uses the heel of the other leg to slide down the shin from the knee smoothly and precisely). Ataxia patients usually have difficulty performing a smooth sliding motion and/or having difficulty maintaining the position of the heel on the shin.

To assess stance, patients are asked to stand at a natural position to observe for truncal sway and/or titubation, which is an uncontrollable shaking movement of the trunk, especially during standing or walking. To bring out mild ataxia in stance exam, patients are instructed to stand with feet together, to stand in a tandem stance, to stand on either foot, or to hop on one foot. A useful test is to ask patients to close eyes while performing these maneuvers. A significant worsening in balance with eyes closed may indicate a component of sensory neuropathy, dorsal column disorders, or vestibulopathy.

The classical gait abnormality in ataxia is a wide-based gait. However, not all the ataxia patients have such gait. With mild ataxia, patients may only exhibit variable stride length and direction. Turning, especially when performed abruptly and rapidly, can sometimes bring out deficits in patients with mild ataxia. A wide-based gait is often a strategy that patient develop in more severe stages of the disease to compensate for loss of balance. The variability of walking direction and step length is a core feature of ataxia gait. The gait abnormalities in different stages of ataxia are demonstrated in Video 82.2. If a patient only experiences difficulty in walking upstairs, downstairs, or running, observing a patient performing such a task will usually yield important information to make a diagnosis.

Examining eye movements is an important component of the cerebellar examination. Specific abnormalities are often associated with different causes of ataxia. (1) Saccadic intrusion in fixed gaze (ie, square wave jerks) can be seen in Friedreich ataxia, (2) horizontal or vertical end-gaze nystagmus can occur in many types of ataxia, (3) hypo- or hypermetric saccades can be observed in many types of ataxia, (4) breakdown of smooth pursuit is often encountered SCA3, (5) slow saccades are typical for SCA2, (6) ophthalmoplegia/ophthalmoparesis that can be observed in sensory axonal neuropathy with dysarthria and ophthalmoplegia [SANDO]), and (7) ptosis can occur in SANDO and mitochondrial ataxia. Among these eye signs, nystagmus and hypo- or hypermetric saccades are most commonly encountered in many ataxic disorders; therefore, these signs can be helpful to differentiate cerebellar ataxia from sensory neuropathy, especially in the early stages of the disease when no cerebellar atrophy is found on neuroimaging. Video 82.3 demonstrates some of the eye movement abnormalities seen in ataxia patients.

The above-mentioned neurologic examination is helpful to establish the presence of ataxia. Other associated signs can, however, be critical to identify the specific etiology. Special attention should be paid to signs of parkinsonism, tremor, dystonia, myoclonus, sensory neuropathy, hyperreflexia, and upgoing toes, which can occur in some types of SCAs and also multiple system atrophy. Other signs during the physical examination can possibly aid the diagnosis, including telangiectasia (for ataxia telangiectasia), splenomegaly (for Niemann-Pick type C), scoliosis, and pes cavus (for Friedreich ataxia). Sensory neuropathy should be emphasized as an important part of the exam as several genetic forms of ataxia have prominent sensory neuropathy without cerebellar atrophy in the early stage of the diseases, such as Friedreich ataxia and *POLG* ataxia.

Once cerebellar ataxia has been established, a step-by-step approach should be implemented to pinpoint the specific causes (Fig. 82.2).

Laboratory Testing

Blood biomarkers can be useful to diagnose nutritional and immune-mediated causes for ataxia. Blood levels of vitamin B_{12} and vitamin E can be tested for vitamin deficiency associated ataxias. Blood vitamin B_1 levels and red blood cell transketolase activity can be measured for thiamine deficiency, but it is not clear whether these lab tests can accurately detect the thiamine deficiency in the brain. Clinicians should have a high clinical suspicion of Wernicke encephalopathy in individuals with a history of alcoholism, malnutrition associated with cancer, and those who have undergone gastric bypass surgery. Empirical treatment with thiamine should be implemented in ataxia patients with altered mental status and nystagmus.

Serum antibody levels can be very helpful to identify specific immune-mediated ataxia. For example, anti–glutamic acid decarboxylase (GAD) antibody can be associated with pure cerebellar ataxia or in the spectrum of stiff person syndrome. Additionally, serum antigliadin antibodies and tissue transglutaminase antibodies are associated with ataxia with gluten sensitivity. Anti-thyroperoxidase antibody can possibly indicate ataxia associated with steroid-responsive encephalopathy. Whether these antibodies are causal is still not entirely clear, but these antibodies are suggestive of an immune etiology for which treatment should be initiated.

Cerebrospinal fluid (CSF) analysis should be performed in acute or subacute ataxia patients with testing for viruses, bacteria, intrathecal immunoglobulin production, pleocytosis, glucose, and protein levels, to identify infectious and inflammatory causes of ataxia. CSF levels of protein 14-3-3 and RTQuic can aid the diagnosis of Creutzfeldt-Jakob disease. Low CSF glucose levels might indicate ataxia with glucose transporter type 1 deficiency, which has very diverse clinical presentations and sometimes predominantly cerebellar ataxia.

If acquired causes of cerebellar ataxia have been excluded and/or there is a family history of ataxia, particularly first-degree relatives, genetic tests should be ordered, which is detailed in the following text.

FIGURE 82.2 Flowsheet for ataxia diagnosis. Abbreviations: ANA, antinuclear antibody; CBC, complete blood count; CSF, cerebrospinal fluid; CT, computed tomography; GAD65, glutamic acid decarboxylase, 65 kDa isoform; HgbA1c, hemoglobin A1c; IgG, immunoglobulin G; mGluR1, metabotropic glutamate receptor 1; MRI, magnetic resonance imaging; PET, positron emission tomography; RPR, rapid plasma reagin; TSH, thyroid-stimulating hormone; vit, vitamin; VDRL, Venereal Disease Research Laboratory; VGCC, voltage-gated calcium channel.

Neuroimaging

Brain magnetic resonance imaging (MRI) is the most commonly employed neuroimaging for ataxia and it used to identify any structural and vascular lesions: brain tumors, abscess, ischemic and hemorrhagic strokes, or demyelinating lesions of multiple sclerosis, and to assess the degree of cerebellar atrophy. Clinicians should evaluate the size of the cerebellum at the vermis, paravermis, and hemispheric regions (Fig. 82.3A-D), which might correspond to clinical symptoms. As the cerebellum degenerates, the foliation of cerebellar lobules becomes prominent. The anterior lobules of the cerebellum are critical for motor control, and the atrophy in this region is often associated with ataxia. On the other hand, the posterior lobules of the cerebellum may be related to the nonmotor features of cerebellar dysfunction such as depression and emotional lability; therefore, atrophy in the posterior lobules in patients might present with prominent cognitive and emotional dysfunction, termed the *cerebellar cognitive affective syndrome*. As mentioned earlier, vermal atrophy might be associated with trunk and gait ataxia, whereas paravermal atrophy might be related to appendicular ataxia. Interestingly, some forms of ataxia may not be associated with cerebellar atrophy on brain MRI, especially in the early stage. These ataxias have predominantly sensory neuronopathy, such as Friedriech ataxia, ataxia with vitamin E deficiency, and *POLG* ataxia.

Besides cerebellar atrophy, other brain MRI findings might indicate a specific diagnosis. A hot cross bun sign (a cross sign

FIGURE 82.3 Neuroimaging of ataxia. Sagittal T1 brain magnetic resonance imaging (MRI) demonstrates cerebellar atrophy in a multiple system atrophy patient. Note that there is prominent cerebellar foliation and sulci in the vermis **(A)**, paravermis **(B)**, and hemisphere **(C)** along with pontine atrophy **(A)**. **D:** Prominent sulci also noted in the axial fluid-attenuated inversion recovery sequence in the same case. **E:** T2 sequence of the axial brain MRI shows the hot cross bun sign in the pons of a case of multiple system atrophy. **F:** T2 sequence of the axial brain MRI demonstrates hyperintensities in the bilateral inferior olivary nuclei in a case of *POLG* ataxia *(arrows)*. T2 sequence of the axial and sagittal MRI demonstrated T2 hypointensity surrounding the brainstem and the cerebellum **(G)** and the spinal cord **(H)** in a case of superficial siderosis. **I:** T1 sequence of the sagittal MRI of the brain showed no cerebellar atrophy but spinal cord atrophy in a case of Friedreich ataxia.

in the pons on T2 brain MRI), although nonspecific, is often seen in multiple system atrophy (Fig. 82.3E). A typical MRI finding in Wernicke encephalopathy is T2 hyperintensity in the mammillary bodies, periaqueductal grey, and paraventricular thalamus. Cerebrotendinous xanthomatosis and adult-onset Alexander disease can have bilateral, periventricular white matter changes. T2 hyperintensity in the bilateral inferior olivary nucleus suggesting hypertrophic neuronal degeneration can occur in *POLG* ataxia, adult-onset Alexander disease, and ataxia with gluten sensitivity (Fig. 82.3F). Special MRI sequences can be helpful to distinguish specific types of ataxia. For example, the gradient echo sequence demonstrating linear hypointensity along the cerebellum, brainstem, and spinal cord is typical of superficial siderosis (Fig. 82.3G,H), and diffusion-weighted imaging showing cortical ribboning is suggestive of Creutzfeldt-Jakob disease. Other than the cerebellum, special attention should be paid to the spinal cord and the brainstem because spinal cord atrophy can be seen in Friedreich ataxia (Fig. 82.3I), and brainstem atrophy is often present in adult-onset Alexander disease.

Other Diagnostic Tests

Other tests to confirm the extracerebellar symptoms might aid in narrowing the differential diagnosis for the etiology of ataxia. Autonomic nervous system testing showing orthostatic hypotension and/or urinary disturbance and a sleep study demonstrating rapid eye movements behavior disorder is helpful to diagnose multiple system atrophy. A dopamine transporter scan can be used to determine whether there is presynaptic dopamine terminal loss. Sensory neuropathy, which may occur in many forms of autosomal recessive ataxia, can be evaluated by electromyography/nerve conduction studies. An electroencephalogram with characteristic periodic sharp wave complex can help diagnose Creutzfeldt-Jakob disease.

ACQUIRED ATAXIA

Cerebellar signs and symptoms result from a variety of insults to the cerebellum and its connections. Broadly, cerebellar dysfunction that is due to specific environmental, toxic, metabolic, or vascular insults is considered acquired ataxias. A list of potential etiologies for acquired ataxia is presented in Table 82.4. As noted in Table 82.4, it is important to determine the acuity of symptom onset and duration of symptoms to determine possible etiologies for ataxia. This is particularly important because some of the acquired causes for ataxia are treatable, particularly when duration of symptoms is brief. Two categories of particularly relevant ataxias are considered here: vascular and immune ataxias.

Cerebellar Stroke

The most common cause for acute cerebellar ataxia is vascular insult to the cerebellum. Vascular etiologies include cerebellar infarcts or hemorrhage. Cerebellar dysfunction may

TABLE 82.4 Acquired Causes of Ataxia

Entity	Diagnostic Process
Vascular disease	History of strokes, imaging
Hypoxic encephalopathy	History of hypoxic episodes
Demyelinating disease	Remitting and relapsing episodes, imaging, CSF analysis
Tumors in the posterior fossa	Imaging, with contrast
Craniovertebral junction anomalies	Imaging
Toxic disorders:	History
Alcohol	
Chemotherapy (5-fluorouracil, ara-C, methotrexate)	
Metals (mercury, bismuth, lithium, lead)	
Solvents (toluene)	
Anticonvulsants (phenytoin, lithium)	
Infectious/inflammatory disease:	History, imaging, serology, CSF analysis
Acute cerebellar ataxia of childhood, acute cerebellitis	History, imaging, CSF analysis
Postinfectious	Imaging, CSF analysis
Bickerstaff encephalitis	Serology
Human immunodeficiency virus	CSF 14-3-3, imaging, electroencephalogram, biopsy
Creutzfeldt-Jakob disease	Small intestine biopsy
Whipple disease	CSF analysis for JC virus
Progressive multifocal leukoencephalopathy	
Autoimmune	Serology
Paraneoplastic	Anti-Hu, anti-Yo, anti-Ri, others
Gluten sensitivity	Antigliadin, antitissue transglutaminase
Anti-GAD ataxia	Anti-GAD
Anti-GluRδ2	Anti-GluRδ2
Superficial siderosis	Imaging
Nutritional	Blood
Vitamin B_1 deficiency	Vitamin B_1 level
Vitamin B_{12} deficiency	Vitamin B_{12} level
Vitamin E deficiency	Vitamin E level

Abbreviations: CSF, cerebrospinal fluid; GAD, glutamic acid decarboxylase.

FIGURE 82.4 Vascular anatomy of the cerebellum. Abbreviations: AICA, anterior inferior cerebellar artery; PICA, posterior inferior cerebellar artery; SCA, superior cerebellar artery.

be a component of a broader stroke syndrome such as due to infarcts resulting from occlusion of the posterior inferior cerebellar artery (vascular supply to the cerebellum summarized in Fig. 82.4). Isolated cerebellar ataxia may result from a branch occlusion of the superior cerebellar artery. Occlusion of the anterior inferior cerebellar artery may result in cerebellar ataxia with deafness on the affected side.

Spontaneous cerebellar hemorrhage most often presents as altered consciousness, with nausea or vomiting due to elevated intracranial pressure, but can present with cerebellar ataxia.

Paraneoplastic and Autoimmune Ataxia

Autoimmune cerebellar syndromes represent a small subset of ataxias. These are however, important to recognize for two reasons. These disorders may be responsive to treatment, particularly when recognized early, and also because some of the autoimmune ataxias help understand disease pathogenesis in inherited forms of ataxia. A subset of autoimmune ataxias is associated with an underlying, often occult malignancy. The neurologic symptoms, believed to be a result of immune cross-reactivity between the tumor and cerebellar antigens, may suggest the presence of a previously unidentified tumor. The ataxia would therefore be considered a paraneoplastic syndrome: a remote effect of an underlying tumor. Specific immune ataxias are described in the following text.

Classic Paraneoplastic Cerebellar Ataxia

The canonical paraneoplastic ataxias are associated with circulating antibodies directed against Yo (also known as *PCA1*), Hu (also known as *ANNA1*), Tr, Ri, CRMP5 (also known as *CV2*), and Ma. The epitopes are intracellular antigens, and there is considerable controversy as to whether the antibodies themselves are causal, versus the manifestation of a T cell–mediated process of autoimmunity. There is a strong association between breast and ovarian cancer with anti-Yo antibodies. Anti-Hu antibodies are strongly associated with detection of small cell lung cancer. The detection of the underlying malignancy may follow the cerebellar syndrome by months to years. An occult malignancy may be detected up to 4 years after symptoms onset; therefore, tumor surveillance at least annually is needed for patients who do not have identifiable malignancy.

Cerebellar Ataxias Resulting from Ion Channel Antibodies

Patients with elevated levels of antibodies directed against voltage-gated calcium channels (VGCC, P/Q, and N type), and voltage-gated potassium channels (Caspr2) may present with cerebellar ataxia. P/Q type calcium channels are particularly highly expressed in Purkinje cells, and in mouse models, reduced channel activity is associated with ataxia. In humans, mutations in *CACNA1A*, the gene encoding the P/Q calcium channel results in episodic ataxia type 2, as well as SCA6. Patients with antibodies against P/Q VGCC may also present with concomitant Lambert-Eaton myasthenic syndrome. Although small cell lung cancer is associated with VGCC-related ataxia, a substantial proportion of patients never have an underlying malignancy.

Ataxia Due to Other Accessible/Cell-Surface Antigens

Unlike the classic paraneoplastic ataxias, antibodies directed against metabotropic glutamate receptor 1 (mGluR1), GluRδ2, and glutamic acid decarboxylase, 65 kDa isoform (GAD65) antibodies are likely causal in disease. Although GAD65 is intracellularly located, access to the antigen is likely possible during synaptic vesicle release. Note that anti-GAD antibody is also associated with diabetes and stiff person syndrome and could coexist with cerebellar ataxia.

Gluten Ataxia

Cerebellar ataxia is a neurologic manifestation of celiac disease, a disorder that is associated with gluten sensitivity. Clinically, gastrointestinal symptoms may or may not be present, with characteristic changes, including changes in villus and crypt morphology, and inflammation in the epithelium on duodenal biopsies. Antibodies directed against gliadin, tissue-transglutaminase (specifically transglutaminase 6) are markers of disease because transglutaminase 6 is important for brain function, whereas antibodies against tissue transglutaminase 2 is a hallmark for celiac disease. Interestingly, a rare genetic form of ataxia results from mutations in transglutaminase 6, causing SCA35. Importantly, a gluten-free diet reduces antibody levels over time and can improve neurologic symptoms.

Neurosarcoidosis

Sarcoidosis (see also Chapter 75) could involve multiple brain regions, including the cerebellum and also meninges, causing cerebellar ataxia and often other associated cranial nerve deficits. Pathologic examination often shows typical granuloma formation (Fig. 82.5).

INHERITED ATAXIAS

Spinocerebellar Ataxia

The spinocerebellar ataxias (SCAs) are a group of dominantly inherited disorders that result from dysfunction and degeneration of the cerebellum and its associated pathways. Although over 40 genes are currently recognized to result in SCA, shared mechanisms for disease pathogenesis exist. The most common SCAs result from a glutamine encoding CAG repeat in the respective

FIGURE 82.5 Neurosarcoidosis. A 51-year-old man with bilateral hearing loss and progressive ataxia. His brain magnetic resonance imaging (MRI) demonstrates hyperintensity in the left medial temporal region on an axial fluid-attenuated inversion recovery sequence **(A)** and cerebellar atrophy on a sagittal T1 sequence **(B)**. Postmortem examination shows that granuloma in the cerebellar cortex **(C)** *(arrow)*, confirming the diagnosis of neurosarcoidosis.

disease genes. In this section, we discuss the varied genetic etiology of SCA and attempt to categorize these disorders based on shared mechanisms of disease. We also summarize the evaluation and management for SCAs.

Introduction

The autosomal dominant cerebellar ataxias (ADCAs), currently known primarily by the designation SCA, are a heterogeneous group of degenerative disorders. Cerebellar ataxia is a core symptom of the SCAs. Other symptoms and signs are variable and disease-specific, including parkinsonism, dystonia, tremor, long-tract signs, peripheral neuropathy, cognitive decline, and seizures (Table 82.5). The polyglutamine (polyQ) ataxias, including SCA1, SCA2, and SCA3, are progressive disorders and lead to shortened lifespan. Several other autosomal dominant ataxias, such as SCA6, cause motor dysfunction, often leading to wheelchair confinement but are not associated with premature death. The first widely accepted systematic classification of dominantly inherited ataxias was proposed in 1993 by Harding. This scheme included ADCA type I in which cerebellar ataxia is variably associated with other neurologic features including dysfunction of the central and/or peripheral nervous system; SCA1, SCA2, and SCA3 all represent type I and are among the most common SCAs. For example, dystonia is commonly seen in SCA3 patients (Fig. 82.6A). In ADCA type II, ataxia is associated with a pigmentary retinopathy; SCA7 is the only ADCA belonging to type II (Fig. 82.6B). ADCA type III is characterized by relatively pure cerebellar ataxia, of which SCA6 is the most common. Although this classification currently has limited clinical utility, it remains useful to classify the ADCAs into those typically presenting with relatively pure ataxia and those accompanied by other neurologic symptoms and signs.

Genetics and Molecular Pathogenesis

An array of genetic causes leads to SCAs. The specific genes and associated features are summarized in Table 82.5. Distinct genes account for more than 35 dominantly inherited ataxias. Groups of disorders can be recognized, however, based on shared mechanisms of disease. These groups include the CAG repeat polyQ ataxias, ataxias associated with noncoding repeats, ataxias associated with ion channel dysfunction, and ataxias associated with mutations in signal transduction molecules.

CAG Repeat Polyglutamine Ataxias

Expansion of a glutamine-encoding CAG repeat accounts for disease in several of SCAs, including SCA1, SCA2, SCA3, SCA6, SCA7, SCA12, SCA17, and dentatorubral pallidoluysian atrophy. SCA1, SCA2, SCA3, and SCA6 represent the majority of SCAs. Additionally, SCA8 likely results from the combined gain-of-function effects of a noncoding CTG repeat expansion leading to toxic messenger RNA and noncanonical translation of peptides from the repeat (so-called RAN translation products) as well as from the generation of a pure polyQ protein from the corresponding CAG repeat on the opposite strand. The polyQ disorders commonly show the phenomenon of anticipation, in which disease onset tends to occur earlier in successive generations. Anticipation is due to CAG repeat instability in the germ line leading to further repeat expansion in successive generations. Anticipation is most prominent in SCA7, which displays marked anticipation of approximately 20 years per generation. The polyQ SCAs frequently are associated with additional neurologic features that vary among the SCAs and even within an SCA, in part due to variation in CAG repeat length (summarized in Table 82.5; video demonstration in ▷ Video 82.4 and ▷ Video 82.5).

It is likely that multiple mechanisms account for disease in the polyQ ataxias. Several mechanisms have been proposed. These include the following:

- Transcriptional dysregulation
- Alterations in membrane excitability due to ion channel dysfunction
- Protein misfolding
- Formation of toxic oligomeric complexes
- Mitochondrial dysfunction
- Impaired axonal transport
- RNA toxicity

Recent work suggests the protein context of the polyQ expansion is important in order to understand disease pathogenesis.

TABLE 82.5 Summary of Clinical Features, Genes, and Molecular Pathogenesis of Autosomal Dominant Ataxias

Name	Symptoms/Signs[a]	Locus	Gene	Protein/Mutation[b]	Normal Function
SCA1	Pyramidal signs Extrapyramidal signs Amyotrophy Ophthalmoparesis	6p23	*ATXN1*	Ataxin-1 (ATXN1) CAG repeats, 41-81 (normal 25-36)	Gene transcription and RNA splicing
SCA2	Slow saccades Extrapyramidal signs Peripheral neuropathy Ophthalmoplegia Pyramidal signs Dementia (rare)	12p24	*ATXN2*	Ataxin-2 (ATXN2) CAG repeats, 35-59 (normal 15-24)	RNA processing
SCA3 (MJD)	Pyramidal signs Amyotrophy Exophthalmos Extrapyramidal signs Ophthalmoparesis	14q24.3-q31	*ATXN3*	Ataxin-3 (ATXN3) CAG repeats, 62-82 (normal 13-36)	Deubiquitinating enzyme
SCA4	Sensory axonal neuropathy Pyramidal signs	16q22.1	Unknown but distinct from SCA31	Unknown	Unknown
SCA5	Pure cerebellar ataxia (late onset) Pyramidal signs (early onset)	11q13	*SPTBN2*	β-III spectrin	Scaffolding protein involved in glutamate signaling
SCA6	Pure cerebellar ataxia Late onset, usually >50 y	19p13.2	*CACNA1A*	Cav2.1 CAG repeats, 21-30 (normal 6-17)	Calcium channel important in Purkinje cells
SCA7	Pigmentary macular degeneration Ophthalmoplegia Pyramidal signs	3p21.1-p12	*ATXN7*	Ataxin-7 CAG repeats, 38-130 (normal 7-17)	Gene transcription
SCA8	Pyramidal signs Diminished vibratory sense Spastic and ataxic dysarthria	13q21.33	*ATXN8OS/ATXN8*	CAG/CTG repeats, 80-250 (normal 15-50) Toxic mRNA Pure polyglutamine protein	Unknown
SCA9	Extrapyramidal signs Ophthalmoplegia Posterior column dysfunction Pyramidal tract signs Central demyelination (one patient)	Unknown	Unknown	Unknown	Unknown
SCA10	Seizures Cognitive/neuropsychiatric impairment Polyneuropathy Pyramidal signs	22q13.31	*ATXN10*	Ataxin-10 Intronic ATTCT repeats, 800-4,500 (normal 10-32)	Involved in neuron survival, neuron differentiation, and neuritogenesis
SCA11	Pure cerebellar ataxia	15q15.2	*TTBK2*	τ-tubulin kinase 2	Serine-threonine kinase Regulates ciliogenesis
SCA12	Upper extremity tremor Mild/absent gait dysfunction Hyperreflexia	5q32	*PPP2R2B*	Protein phosphatase PP2A CAG repeats in 5′-UTR, 51-78 (normal 7-32)	Serine-threonine phosphatase Negative control of cell growth and division
SCA13	Intellectual disability (in French pedigree) Pure cerebellar ataxia (in Filipino pedigree)	19q13.3-13.4	*KCNC3*	Kv3.3	Potassium channel involved in regulating Purkinje cell excitability
SCA14	Pure cerebellar ataxia Rare chorea and cognitive deficits	19q13.4	*PRKCG*	Protein kinase Cγ	Neuronal serine-threonine protein kinase
SCA15/ SCA16	Pure cerebellar ataxia Rare tremor or cognitive impairment	3p26.1	*ITPR1*	Inositol 1,4,5-triphosphate receptor type 1	Intracellular calcium channel Regulation of neuronal excitability
SCA17/ HDL4	Chorea Dementia Extrapyramidal features Hyperreflexia Psychiatric symptoms	6q27	*TBP*	TATA box-binding protein CAG repeats, 46-63 (normal 25-42)	Gene transcription
SCA18/ SMNA	Posterior column dysfunction Amyotrophy Early onset, usually <20 y Hyporeflexia	7q22-q32	Unknown	Unknown	Unknown

TABLE 82.5 Summary of Clinical Features, Genes, and Molecular Pathogenesis of Autosomal Dominant Ataxias *(continued)*

Name	Symptoms/Signs[a]	Locus	Gene	Protein/Mutation[b]	Normal Function
SCA19/ SCA22	Pure cerebellar ataxia Cognitive impairment Myoclonus Postural tremor	1p13.3	*KCND3*	Kv4.3	Potassium channel involved in regulating neuronal excitability
SCA20	Spasmodic dysphonia or spasmodic coughing Palatal tremor	11p11.2-q13.3	Unknown	Gene duplication	Unknown
SCA21	Early onset Cognitive impairment Akinesia Resting tremor Rigidity Dysgraphia Hyporeflexia Postural tremor	7p21.3-p15.1	Unknown	Unknown	Unknown
SCA23	Late onset, usually >50 y Decreased vibratory sense	20p13	*PDYN*	Prodynorphin	Processed to form opioid peptides that bind to κ-type opioid receptors
SCA25	Areflexia Peripheral sensory neuropathy	2p21-p15	Unknown	Unknown	Unknown
SCA26	Pure cerebellar ataxia	19p13.3	*EEF2*	Eukaryotic translational elongation factor 2	Protein synthesis
SCA27	Orofacial dyskinesia Cognitive impairment Tremor	13q34	*FGF14*	Fibroblast growth factor 14	Interacts with voltage-gated sodium channels Regulates Purkinje neuron excitability
SCA28	Early onset, usually <20 y Hyperreflexia Ophthalmoparesis Ptosis	18p11.22-q11.2	*AFG3L2*	ATPase family gene 3-like 2	Mitochondrial protein synthesis
SCA29	Congenital Nonprogressive	3p26.1	*ITPR1*	Inositol 1,4,5-triphosphate receptor	Intracellular calcium channel Regulation of neuronal excitability
SCA30	Late onset, usually >50 y Pure cerebellar ataxia	4q34.3-q35.1	Unknown	Unknown	Unknown
SCA31	Pure cerebellar ataxia Late onset, usually >50 y Sensorineural hearing loss	16q22	*BEAN1* and *TK2*	Brain expressed, associated with NEDD4 Thymidine kinase 2 TGGAA repeat in intron shared by both genes	Unknown
SCA32	Cognitive impairment if onset <40 y Azoospermia	7q32-q33	Unknown	Unknown	Unknown
SCA34	Skin erythema and keratosis Nystagmus Decreased DTRs	6p12.3-q16.2	*ELOVL4*	Elongation of very long chain fatty acids protein 4	Fatty acid synthesis
SCA35	Pyramidal signs Pseudobulbar palsy	20p13	*TGM6*	Transglutaminase 6	Posttranslational modifications of glutamine residues
SCA36	Lower motor neuron involvement Tongue atrophy	20p13	*NOP56*	Nucleolar protein 56 Intronic GGCCTG repeat	Pre-mRNA processing
SCA37	Abnormal vertical eye movements Nystagmus	1p32.2	*DAB1*	Drosophila homolog of disabled 1	Microtubule function, neuronal migration
SCA38	Pure cerebellar ataxia Axonal neuropathy	6p12.1	*ELOVL5*	Elongation of very long chain fatty acids protein 5	Fatty acid synthesis
SCA39	Spasticity Horizontal gaze palsy	11q21-q22.3	Unknown	Unknown	Unknown
SCA40	Spasticity	14q32.11	*CCDC88C*	DAPLE	Signal transduction regulation

TABLE 82.5 Summary of Clinical Features, Genes, and Molecular Pathogenesis of Autosomal Dominant Ataxias *(continued)*

Name	Symptoms/Signs[a]	Locus	Gene	Protein/Mutation[b]	Normal Function
SCA41	Pure cerebellar ataxia	4q27	*TRPC3*	Transient receptor potential cation channel subfamily c member 3 (TRPC3)	Ion channel involved in setting membrane excitability
SCA42	Pure cerebellar ataxia in the majority of patients	17q21	*CACNA1G*	Cav3.1	Calcium channel involved in setting membrane excitability
SCA43	Peripheral neuropathy	3q25	*MME*	Membrane metalloendopeptidase	Inactivates peptide hormones
SCA44	Pure cerebellar ataxia	6q24	*GRM1*	Metabotropic glutamate receptor 1	G-protein–coupled receptor involved in glutamate signaling
SCA45	Pure cerebellar ataxia	5q33	*FAT2*	Homolog of Drosophila fat tumor suppressor 2	Tumor suppressor gene
SCA46	Sensory ataxic neuropathy Cerebellar dysarthria in some	19q13.2	*PLD3*	Phospholipase D family, member 3	Membrane protein involved in APP processing
SCA47	Pure cerebellar ataxia	1p35.2	*PUM1*	Homolog of Drosophila pumilio 1	RNA binding protein that negatively regulates ATXN1
SCA48	Cognitive dysfunction	16p13.3	*STUB1*	STIP1 homologous and U box containing protein 1	E3 ubiquitin ligase that promotes ubiquitylation
DRPLA	Myoclonic epilepsy Choreoathetosis Dementia	12p13.31	*ATN1*	Atrophin 1 CAG repeats, 49-75 (normal 7-23)	Transcriptional coregulator

Abbreviations: DRPLA, dentatorubral pallidoluysian atrophy; HDL4, Huntington disease-like 4; MJD, Machado-Joseph disease; mRNA, messenger RNA; PP2A, protein phosphatase 2; SCA, spinocerebellar ataxia; SMNA, sensorimotor neuropathy with ataxia; UTR, untranslated region.
[a]Not all patients have all the symptoms/signs mentioned.
[b]Mutation refers to point mutations in the respective genes, unless otherwise specified.

FIGURE 82.6 Associated signs and symptoms in spinocerebellar ataxias (SCAs). Hand dystonia in an SCA3 patient **(A)** and pigmentary retinal degeneration in an SCA7 patient **(B)**.

For example, in SCA1, the polyQ expansion alone is insufficient to cause disease if the protein interaction of the disease associated protein ATXN1 is disrupted.

Ataxias Associated With Noncoding Repeats

Expansion of repeats in nontranscribed regions likely underlies disease in SCA8, SCA10, SCA12, SCA31, and SCA36. Recent work has suggested that repeat associated non-AUG translation (RAN translation) may play a role in both noncoding RNA and in CAG repeat containing genes. These noncoding RNAs elicit a variety of toxic function, leading to cerebellar dysfunction.

Ataxias Associated With Ion Channel Dysfunction

Dysfunction of ion channels has been implicated in the pathogenesis of several SCAs. In some cases, channel dysfunction directly reflects ion channel mutations, whereas in others secondary channel dysfunction has been implicated.

- SCA5 results from mutations in the β-III spectrin gene. The disease protein is highly expressed in Purkinje cells and functions to stabilize the Purkinje cell–specific glutamate transporter. In SCA5, these neurons also exhibit reduced spontaneous firing and smaller sodium currents potentially also contributing to disease. In a transgenic mouse model of SCA5, Purkinje cell dysfunction appears to be related to β-III spectrin interaction with and dysregulation of the mGluR1.
- SCA6 is caused by polyQ expansion in a neuronal P/Q-type VGCC, Cav2.1. The mechanism by which this mutation causes disease remains unclear but may include both altered channel function due to haploinsufficiency and gain of function associated with a polyQ expansion harboring C-terminal fragment. Recent work in SCA6 has identified alternative transcript of the *CACNA1A* gene that results in a transcription factor, α1ACT, which coordinates expression of a program of genes involved in Purkinje cell development.
- SCA13 is caused by mutations in the *KCNC3* gene, which encodes the voltage-gated potassium channel Kv3.3. This potassium channel is expressed throughout the brain but is enriched in Purkinje cells, a susceptible cell population in SCA13. Mutations are thought to lead to a dominant-negative suppression of current through this channel or altered channel gaiting.
- SCA15/16 results from mutations in the inositol 1,4,5-triphosphate receptor 1, an intracellular ligand-gated calcium channel highly expressed in Purkinje cells.
- SCA19/22 results from loss-of-function mutations in the *KCND3* gene, encoding the Kv4.3 potassium channel. Loss of channel function is the presumed cause of ataxia in this disorder.
- SCA27 is caused by mutations in *FGF14* that likely lead to abnormal expression of voltage-gated sodium channels in cerebellar neurons. Mice lacking FGF14 are noted to be phenotypically similar to humans with SCA27 and have altered Purkinje cell firing attributed to reduced expression of Nav1.6, a sodium channel necessary for repetitive firing.
- SCA41 is caused by mutations in *TRPC3*, a nonselective cation channel, that is, enriched in the cerebellum and influences Purkinje cell membrane excitability.
- SCA42 is caused by mutations in the calcium channel, Cav3.1, which is highly expressed in the cerebellum.
- SCA44 is caused by mutations in *GRM1*, which codes for mGluR1. Notably, the abnormal gain of function of mGluR1 in SCA44 differs from the loss of mGluR1 function seen in SCA5.

Ataxias Associated With Mutations in Signal Transduction Molecules

Mutations in genes implicated in signal transduction cause ataxia in SCA11, SCA12, SCA14, SCA23, and SCA40, although alterations in signal transduction pathways likely are indirectly involved in most SCAs.

- SCA11 is caused by loss-of-function mutations in *TTBK2*, a serine-threonine kinase in the casein kinase 1 family. There is evidence that this enzyme regulates the initiation of ciliogenesis.
- SCA12 is caused by a CAG repeat expansion in the 5′-untranslated region of the protein phosphatase PP2A. The exact mechanism by which this expansion leads to disease is unclear. There are likely shared features with other noncoding repeat disorders.
- SCA14 results from mutations in protein kinase C γ, an isoform highly expressed in Purkinje cells. Data from a mouse model suggests that this protein is important for synapse pruning, synaptic plasticity, and synaptic transmission in Purkinje cells.
- SCA23 results from mutations in *PDYN*, which encodes prodynorphin, an opioid neuropeptide precursor protein that is processed to α-neoendorphin and dynorphins A and B. Putative mechanisms of disease based on cellular models include glutamate neurotoxicity causing Purkinje cell degeneration and ataxia induced by alterations in a dynorphin A activity and/or impaired secretory pathways by mutant PDYN.
- SCA40 is caused by a missense mutation in *CCDC88C* that results in a gain of function ultimately triggering c-Jun N-terminal kinase–mediated neuronal apoptosis.

Animal models have significantly contributed to current knowledge of the SCAs, including the underlying pathophysiology. These models have provided a useful mechanism for understanding how genetics inform disease processes and will likely serve as critical tools for developing potential therapies in the future.

Genetic Testing

Although there is considerable phenotypic variability within the SCAs, certain clinical features often are helpful in prioritizing genetic testing (see Table 82.5). Geographic origin and ethnicity are also frequently helpful (eg, SCA3 in Brazil/Portugal, SCA2 in Cuba). In general, a reasonable approach is to pursue genetic testing in a sequential, stratified fashion based on phenotype. This is most applicable in cases where a clearly associated feature is present in addition to ataxia, such as vision loss in SCA7. Most associated features in other SCAs do not reach this level of reliability, and in these cases, screening for the most common autosomal dominant SCAs as a first step is likely of higher yield.

A suggested approach for genetic testing in sporadic and familial ataxias is to first test for the most common SCAs, such as types SCA1, SCA2, SCA3, SCA6, and SCA7, as well as for Friedreich ataxia, before pursuing testing such as whole exome sequencing (see the following text).

Currently, there are commercially available targeted genetic tests for SCA1, SCA2, SCA3, SCA4, SCA5, SCA6, SCA7, SCA8, SCA10, SCA11, SCA12, SCA13, SCA14, SCA15/16, SCA17, SCA18, SCA19/22, SCA23, SCA27, SCA28, SCA29, SCA31, SCA35, SCA36, and dentatorubral pallidoluysian atrophy. Recently, technology for genome-wide sequencing has become

available clinically. Sequencing the exome, the approximately 1% of the genome expressed as protein, allows for simultaneous evaluation of the entire human genome to localize protein-altering sequence variation. If acquired causes have been fully evaluated and testing for the most common heritable causes is unrevealing, whole exome sequencing is a reasonable next step. Limitations of this technology include its relatively poor ability to detect certain types of mutations including repeat expansions, noncoding variants, and large deletions/duplications.

Autosomal Recessive Ataxia

Autosomal recessive ataxia can be divided into three categories: (1) cerebellar ataxia with predominant sensory neuronopathy, (2) cerebellar ataxia with sensorimotor axonal neuropathy, (3) cerebellar ataxia without sensory neuropathy. Table 82.6 lists common causes of autosomal recessive ataxia in the respective categories. As compared to autosomal dominant ataxia, recessive ataxia usually has earlier age of onset in childhood and presents with involvement of retina, cerebral cortex, basal ganglia, corticospinal tracts, and peripheral nerves, leading to complex multisystem phenotypes. The involvement of peripheral nerves is the key feature of the exam in identifying the genetic basis of autosomal recessive ataxia as detailed in the following text.

Cerebellar Ataxia With Predominant Sensory Neuropathy (Friedreich Ataxia)

The prototypical disease for the category of cerebellar ataxia with predominant sensory neuronopathy is Friedreich ataxia, which is the most common recessive ataxia. Friedreich ataxia patients have an age of onset from childhood to third decade. Clinical features often include pes cavus, scoliosis, square wave jerks, areflexia, vibratory, and proprioceptive sensory loss. Large fiber sensory neuronopathy is a key feature of Friedreich ataxia with pain and temperature sensation relatively preserved. Approximately 25% of patients with Friedreich ataxia can have atypical presentation with onset after age 25 years, slow progression, and prominent spasticity with hyperreflexia. Diabetes and cardiomyopathy are also common in Friedreich ataxia. Impaired glucose tolerance has been found in one-third of Friedreich ataxia patients, whereas overt diabetes occurs in 15%. Another systemic feature is hypertrophic cardiomyopathy, which can present as arrhythmia or heart failure. Therefore, routine glucose tolerance test and cardiac evaluation, including electrocardiogram and echocardiogram, are indicated in Friedreich ataxia patients.

Friedreich ataxia is caused by an expanded intronic GAA repeat in the first exon of the *FXN* gene, which results in inefficient production of frataxin protein and leading to disturbed mitochondrial function. About 5% of Friedreich ataxia patients have one allele carrying a point mutation in *FXN* gene and another allele with a repeat expansion. Therefore, a neurologist should still have a high suspicion of Friedreich ataxia even if the expanded repeat is only detected in one allele, in patients who otherwise exhibit characteristic clinical features of Friedreich ataxia. Frataxin is a protein that is ubiquitously expressed; therefore, blood or saliva frataxin levels have been used as biomarkers for target engagement for therapy development in Friedreich ataxia.

Friedreich ataxia belongs to a group of autosomal recessive ataxias with predominant sensory neuronopathy (see Table 82.6). Other diseases in this group include SANDO, ataxia

TABLE 82.6 Common Causes of Autosomal Recessive Cerebellar Ataxia

Disease	Genetic Mutations	Age at Onset	Associated Clinical Features
Cerebellar Ataxia With Predominant Sensory Neuronopathy			
Friedreich ataxia	Repeat expansions in intron 1 of *FXN* gene	From childhood to third decade	Pes cavus, scoliosis, square wave jerks, hyporeflexia, spasticity (adult onset)
Sensory axonal neuropathy with dysarthria and ophthalmoplegia	*POLG* mutations	20-60 y	Ophthalmoplegia, dysarthria, ptosis, myoclonus, epilepsy
Ataxia with vitamin E deficiency	*TTPA* mutations	2-50 y	Retinitis pigmentosa, head tremor
Abetalipoproteinemia	*MTP* mutations	Birth	Diarrhea, neonatal steatorrhea
Cerebellar Ataxia With Sensorimotor Axonal Neuropathy			
Ataxia telangiectasia	*ATM* mutations	<5 y	Telangiectasia, chorea, dystonia, susceptibility to infections and cancer, radiosensitivity, elevated α-fetoprotein
Ataxia with oculomotor apraxia type 1	*APTX* mutations	<20 y	Oculomotor apraxia, chorea, dystonia
Ataxia with oculomotor apraxia type 2	*SETX* mutations	From childhood to third decade	Oculomotor apraxia, chorea, dystonia, elevated α-fetoprotein
Cerebrotendinous xanthomatosis	*CYP27* mutations	Childhood	Spasticity, mental retardation, tendon xanthoma, chronic diarrhea, premature cataract
Late-onset GM2 gangliosidosis	*HEXA* or *HEXAB* mutations	15-45 y	Spasticity, weakness, dystonia, epilepsy, cognitive decline, psychosis
Cerebellar Ataxia Without Neuropathy			
Autosomal recessive cerebellar ataxia type 1	*SYNE1* mutations	From second to fifth decade	Spasticity, lower motor neuron signs
Autosomal recessive cerebellar ataxia type 2	*ADCK3* mutations	<10	Mental retardation, myoclonus, epilepsy, exercise intolerance
Niemann-Pick type C	*NPC1* and *NPC2* mutations	From first to third decade	Vertical supranuclear ophthalmoplegia, splenomegaly, dystonia, cognitive decline

FIGURE 82.7 The major pathomechanisms of autosomal recessive cerebellar ataxia.

with vitamin E deficiency, and abetalipoproteinemia. In this particular group, cerebellar atrophy might not be evident on brain MRI, at least in the early stages of disease. SANDO is caused by *POLG* mutations. The age of onset is in adulthood often with ophthalmoplegia, ptosis, myoclonus, and epilepsy. Bilateral inferior olivary nucleus T2 hyperintensity can sometimes be observed on a brain MRI (**Fig. 82.3F**). Ataxia with vitamin E deficiency is associated with head tremor and retinitis pigmentosa. Patients with abetalipoproteinemia have very early disease onset with neonatal steatorrhea.

Cerebellar Ataxia with Sensorimotor Axonal Neuropathy

The second group of autosomal recessive ataxia is cerebellar ataxia with sensorimotor axonal neuropathy. This group includes ataxia telangiectasia, ataxia with oculomotor apraxia types 1 and 2, cerebrotendinous xanthomatosis, and late-onset GM2 gangliosidosis (see **Table 82.6**). The age of ataxia onset is variable in this group, but sensorimotor neuropathy is often present. Other features such as chorea, dystonia, and spasticity are common observed. α-Fetoprotein levels are elevated in ataxia telangiectasia and ataxia with oculomotor apraxia type 2, which can be used as a screening tool for these diseases. Ataxia telangiectasia patients have increased risk for cancer and infection, in addition to sensitivity to radiation. Oculomotor apraxia may be seen in the ataxias with oculomotor apraxia. Increased cholestanol levels and hexosaminidase activity deficiency are useful diagnostic tests for cerebrotendinous xanthomatosis and late-onset GM2 gangliosidosis, respectively.

Cerebellar Ataxia Without Neuropathy

The third category of recessive ataxia is those without neuropathy. This includes autosomal recessive cerebellar ataxia type 1 with *SYNE1* mutations, autosomal recessive cerebellar ataxia type 2, and Niemann-Pick type C. Autosomal recessive cerebellar ataxia type 1 is usually adult onset, with upper or lower motor neuron signs, pes cavus, and scoliosis. Autosomal recessive cerebellar ataxia type 2 can present with mental retardation, myoclonus, and epilepsy. Niemann-Pick type C patients have characteristic vertical supranuclear ophthalmoplegia (▶ **Video 82.3**) in addition to mental retardation, dystonia, and cognitive decline.

Autosomal recessive ataxia can sometimes be identified in patients without a family history of ataxia. In a study of a large cohort of sporadic ataxia, autosomal recessive cerebellar ataxia type 1 with *SYNE1* mutations is the most commonly identified and accounts for 4% of cases. There is also an increasing recognition that mutations in genes traditionally associated with autosomal recessive spastic paraplegia can also produce ataxia. One such example is mutations in *SPG7*, which can cause isolated cerebellar ataxia.

The disease pathogenic mechanism for autosomal recessive ataxia is usually the loss of function of protein associated with genetic mutations; therefore, the therapeutic development has been focused on (1) enhancing or stabilizing the deficient protein, (2) exogenous protein expression by gene therapy, and (3) reducing toxic substrates as the result of protein function deficiency. The results of loss of function of proteins in autosomal recessive ataxia usually lead to three major biologic consequences: (1) impaired mitochondrial function, (2) impaired DNA repair, and (3) impaired lipid metabolism (Fig. 82.7). Dysfunction of these pathways may partially explain the selective vulnerability of the cerebellum in these diseases, and targeting these downstream pathways might pose opportunities to treat a broad range of autosomal recessive ataxia.

Other Inherited Ataxias

X-Linked Ataxia

The most common X-linked ataxia is fragile X–associated tremor and ataxia syndrome (FXTAS), which is caused by 55 to 200 CGG repeat expansion within the *FMR1* gene. Expansion of this unstable repeat in *FMR1* in successive generations, can lead to fragile X syndrome, characterized by intellectual disability in childhood. Premature ovarian failure in women can also be a clinical presentation of repeat expansions in *FMR1* gene. Therefore, FXTAS should be considered in the context of family history of mental retardation and premature ovarian failure. Parkinsonism and autonomic dysfunction can also occur; therefore, FXTAS should be on the differential diagnosis for multiple system atrophy. T2 hyperintensity in the middle cerebellar peduncles (Fig. 82.8) and corpus callosum in the brain MRI are characteristic FXTAS and can help make the diagnosis.

Mitochondrial Ataxia

Mitochondrial DNA mutations can also cause ataxia. The common causes in this category are Kearns-Sayre syndrome, myoclonus epilepsy with ragged-red fibers, and mitochondrial encephalopathy,

FIGURE 82.8 Axial brain magnetic resonance imaging fluid-attenuated inversion recovery sequence demonstrates hyperintensity of bilateral middle cerebellar peduncles in a patient with fragile X–associated tremor and ataxia syndrome.

lactic acidosis, and stroke-like episodes. Because genetic mutations in the mitochondrial genome can be tissue specific (ie, heteroplasmy), a muscle biopsy should be performed because mitochondrial defects are more likely to be detected in the nondividing cells such as muscles, for which biochemical assessment and mitochondrial DNA content determination can be performed.

Episodic Ataxia

Episodic ataxia (types 1-8) constitutes a group of dominantly inherited causes for intermittent ataxia attacks, lasting from minutes to days. There might be underlying progressive ataxia in addition to episodic attacks. The pathogenic mechanism of episodic ataxias is due to either channelopathy (episodic ataxia types 1 and 2) or dysfunctional glutamate transport (episodic ataxia type 6). Interestingly, episodic ataxia is caused by mutations in *CACNA1A* gene, and mutations of such genes can have diverse disease presentations, including SCA6 and familial hemiplegic migraine, indicating the importance of the encoded protein, Cav2.1, in cerebellar neuronal function.

Other major differential diagnoses for episodic ataxia are multiple sclerosis and psychogenic ataxia.

Cerebellar Ataxia, Neuropathy, and Vestibular Areflexia Syndrome

Recent work has identified biallelic pentanucleotide expansions in the *RFC1* gene as a common cause for a syndrome consisting of cerebellar ataxia, sensory neuropathy/neuronopathy, and vestibular areflexia. Surprisingly, a significant proportion of late-onset sporadic ataxias result from the same biallelic mutations in *RFC1*. In a Caucasian population, biallelic mutations in *RFC1* should be considered in cases of sporadic adult-onset ataxia, particularly if neuropathy and vestibulopathy are also present.

Degenerative Ataxia

Degenerative forms of ataxia usually occur after the age of 60 years in individuals without a family history of ataxia. In this category, multiple system atrophy and idiopathic late-onset cerebellar ataxia are the two most common diseases with degenerative pathology.

Multiple System Atrophy

Multiple system atrophy is a disease involving multiple brain regions resulting in cerebellar ataxia, parkinsonism, autonomic instability (orthostatic hypotension, impotence, urinary frequency, urgency, and incontinence), and pyramidal signs (hyperreflexia and upgoing toes). The pathologic hallmark of multiple system atrophy is glial cytoplasmic inclusions, containing α-synuclein, in the oligodendrocytes, along with microglial activation, reactive astrogliosis, and neuronal death in the basal ganglia and the cerebellum. Depending on the predominant clinical features, multiple system atrophy can be divided into multiple system atrophy–parkinsonism type or multiple system atrophy–cerebellar type (MSA-C). In this section, we discuss MSA-C, in which ataxia is predominant feature of disease at symptom onset. MSA-C constitutes approximately 13% to 42% of all multiple system atrophy cases, but this can vary in different ethnic backgrounds. MSA-C generally has a slower disease progression than multiple system atrophy–parkinsonism. In the early stages of the disease, patients may present with relatively isolated cerebellar ataxia. Therefore, the history and neurologic examination should focus on searching for signs of parkinsonism, autonomic dysfunction, and upper motor neuron dysfunction. Rapid eye movement sleep behavior disorder is often present, which can be very helpful to indicate the underlying synucleinopathy associated with multiple system atrophy. Respiratory stridor and obstructive sleep apnea can be present and sometimes can be a cause of death. Therefore, for patients with onset of cerebellar ataxia later in life, autonomic tests and sleep studies can provide additional evidence to support the diagnosis of multiple system atrophy when clinical symptoms are not yet evident. The brain MRI in multiple system atrophy cases often shows the "hot cross bun" sign (see **Fig. 82.3E**). This sign may not be evident in the early stages of disease but can show up later after the disease progresses. ▶ **Video 82.6** demonstrates a patient with multiple system atrophy.

Idiopathic Late-Onset Cerebellar Ataxia

Multiple system atrophy is a disease with relatively fast progression with death within 6 to 10 years of symptom onset. On the other hand, idiopathic late-onset cerebellar ataxia is a disease with slower progression and usually does not compromise life span. Idiopathic late-onset cerebellar ataxia patients will not usually develop other neurologic features such as autonomic dysfunction or parkinsonism. Practically, the presence of parkinsonism and autonomic dysfunction in elderly ataxia patients often suggests a poor prognosis because the diagnosis is likely to be multiple system atrophy. If there is no parkinsonism or autonomic dysfunction within 5 years of the onset of ataxia, these patients are likely to follow a benign clinical course with the diagnosis of idiopathic late-onset cerebellar ataxia. Within newer technologies such as exome sequencing, a subset of the idiopathic late-onset ataxias have now been determined to have a genetic basis.

Essential tremor is a very common movement disorder, characterizing primarily by upper extremity tremor. Recent work has challenged the idea that this is a disorder that presents solely with tremor because patients with essential tremor can have difficulty in tandem gait, particularly in individuals with more severe disease. Kinematic analysis has revealed imprecise foot placement consistent with an ataxic gait, suggesting true cerebellar dysfunction. Degenerative changes in the cerebellum, including cerebellar Purkinje cell loss, have been identified in the postmortem brain

in essential tremor, but to a lesser degree when compared to patients with SCAs and multiple system atrophy; therefore, essential tremor could be considered a cerebellar disorder.

Psychogenic Ataxia

Psychogenic ataxia is a psychogenic movement disorder. Patients usually experience a major life event preceding the onset of ataxia symptoms. They usually can recall the exact date or time when the first symptom occurred. The disease course is often fluctuating or episodic in nature. There are four core features of psychogenic ataxia: (1) inconsistency, (2) variability, (3) distractibility, (4) associated atypical features. An example of inconsistency is a patient who might not be able to walk well but might be able to run or hop on either foot, which requires better balance than walking. Variability and episodic neurologic attacks can also suggest psychogenic ataxia, with a major differential diagnosis of episodic ataxia and multiple sclerosis in mind. Distractibility means that patients might perform much better when distracted and/or when instructed to perform other tasks such as counting during the ataxia examination. Finally, psychogenic ataxia has many "atypical" features, not seen in other causes of ataxia; for example, extreme exhaustion, light sensitivity, or give-way weakness. Identification of psychogenic ataxia is very important to avoid further genetic or other testing and treatment of ataxia. Referral to a psychiatrist is critical in the care of these patients.

MANAGEMENT AND FUTURE DEVELOPMENTS

The treatment for ataxia can be categorized into symptomatic and disease-modifying therapies. Disease-modifying therapy exists for ataxia, especially for acquired cases; for example, thiamine for Wernicke encephalopathy, gluten-free diet for ataxia associated with gluten sensitivity, and intravenous immunoglobulin, plasmapheresis, and other immunosuppressive agents, such as rituximab for anti-GAD ataxia and paraneoplastic ataxia. There are some disease-modifying therapies for genetic ataxia, particularly autosomal recessive ataxias: vitamin E replacement for ataxia of low vitamin E levels (ataxia associated with vitamin E deficiency and abetalipoproteinemia), miglustat for Niemann-Pick type C, chenodeoxycholic acid for cerebrotendinous xanthomatosis, dietary modification to restrict phytanic acid for Refsum disease. Glucose transporter type 1 deficiency is autosomal dominantly inherited disorder with diverse neurologic presentation, including ataxia, and can be treated with ketogenic diet.

Two important avenues of research hold promise in the treatment of the SCAs. Nucleotide-based strategies to reduce expression of pathogenic gene products have been applied to the SCAs, including RNA interference and antisense oligonucleotides. Recent success with antisense oligonucleotides to reduce expression of the SCA1, SCA2, and SCA3 gene products in mouse models of disease provide hope for eventual testing of similar disease gene-silencing molecules in human trials. The second avenue for treatment involves the identification of shared neuronal dysfunction tied to dysfunction of specific potassium channels. Targeting potassium channels may provide an avenue for treatment of symptoms in a variety of ataxias.

There is a pipeline of therapy development for Friedreich ataxia that target various molecular pathways, which includes (1) improving mitochondrial function and reducing oxidative stress, (2) modulating frataxin-controlled metabolic pathways, (3) stabilizing frataxin protein, or (4) increasing *FXN* gene expression.

Certain commonly used treatment options are often used by ataxia experts. Riluzole 50 mg twice a day has been shown to improve dysarthria and gait ataxia. Liver function monitoring is necessary while patients are treated with riluzole. Varenicline 1 mg twice a day is suggested to help ataxia in SCA3 patients and could benefit patients with other forms of ataxia. The side effect of depression should be closely monitored, particularly as many SCA3 patients already suffer from depression. 4-Aminopyridine 15 mg daily has been shown to be effective to suppress the number of attacks in episodic ataxia type 2 and may be useful to treat nystagmus in ataxia patients. Other medications such as amantadine, baclofen, and chloroxazone can also be tried to treat ataxia. For the dizziness sensation, commonly seen in cerebellar ataxia, neuropathy, and vestibular areflexia syndrome, or anti-GAD ataxia, diazepam might be useful. Symptoms other than ataxia, such as tremor, dystonia, and depression, should be identified and treated with conventional symptomatic therapy. For instance, postural tremor can be treated by primidone or propranolol, and dystonia using botulinum toxin injections.

Exercise can provide benefit for ataxia patients as exercise has been shown to enhance the lifespan in an SCA1 mouse model of disease. Coordinated training and balance exercise has been demonstrated to provide long-standing benefits for ataxia patients, and these exercises focus on the core strength and balance. Whether aerobic and other forms of exercise will also have additional benefits remains to be tested in the future.

Cerebellar ataxias represent a heterogeneous group of disorders. Recognition of the time course of symptoms, in addition to knowing if motor symptoms are truly cerebellar in origin is critical to make the diagnosis and identify potentially treatable entities. Early recognition of immune causes of ataxia is important to prevent progressive disability. A significant subset of the ataxias are due to genetic causes. Knowing the genetic basis for ataxia can help with planning for future disability. Although no approved pharmacologic treatment currently exists for inherited and degenerative ataxia, research on the horizon is promising for both treatment of symptoms and slowing disease progression. Intensive balance training is the mainstay of current treatment and should be recommended for all patients with ataxia.

Videos can be found in the companion e-book edition. For a full list of video legends, please see the front matter.

83 Tardive Dyskinesia and Other Neuroleptic-Induced Syndromes

Un Jung Kang and Stanley Fahn

KEY POINTS

1. Dopamine receptor antagonists can produce a variety of motor and sensory abnormalities as an iatrogenic condition.
2. Dopamine receptor antagonists produce parkinsonism and other side effects associated with hypodopaminergic state that are reversible upon discontinuation of the offending medication.
3. Tardive dyskinesia syndrome usually occurs after chronic exposure to dopamine receptor antagonists and often persists even after discontinuation of the offending agent.
4. The pathophysiology of tardive dyskinesia is still poorly understood but may involve maladaptive plasticity of brain circuits.
5. The best established treatments for tardive dyskinesia are tetrabenazine derivatives that deplete monoamines.

INTRODUCTION

Neuroleptics are medications that are named for its neurologic side effects of inducing parkinsonism (called drug-induced parkinsonism), a variety of other movement disorders, sensory disorders and an altered state of consciousness with fever. The most common neuroleptic-induced movement disorders are acute dystonic reactions (involuntary sustained twisting movements and postures), parkinsonism, and tardive dyskinesia syndromes (TDS). TDS can manifest as repetitive rhythmic movements most often affecting the mouth and limbs as well as other types of movement disorders (Table 83.1). TDS have variable delayed onset after the initiation of the offending drugs and persists even after they are discontinued (see Table 83.1). The common pathophysiologic mechanisms of neuroleptics are binding to and antagonizing dopamine D_2 receptors. The dopamine receptor blocking agents (DRBAs) are used not only as antipsychotic agents, such as the phenothiazines and the butyrophenones, but also for gastrointestinal disorders, such as metoclopramide. By definition, these disorders are iatrogenic and hence can be prevented, their risk minimized, and potentially reversed by making the diagnosis early and instituting appropriate treatment. Although the second-generation antipsychotics, often also called *atypical* antipsychotics have been developed to reduce these side effects, they are not entirely free of them.

EPIDEMIOLOGY

The prevalence of neuroleptic-induced neurologic disorders ranges from 20% to 50%. Drug-induced parkinsonism is the most common form. Neuroleptic exposure increases the risk of parkinsonism by twofold, increasing with age and female gender. Acute dystonic reactions occur in about 2% to 5% of patients exposed to neuroleptics, more commonly in children and young adults and in males than females. TDS may occur in about one quarter of patients exposed to these drugs but estimation of true incidence and prevalence vary and is often confounded by the fact that DRBAs mask the clinical manifestation of TDS. Classic tardive dyskinesia involving orofacial movements is most common with an annual incidence rate of about 5% in the first 4 to 5 years. TDS increase with cumulative exposure to DRBAs factoring in the dosage and the duration of treatment. Advanced age is the most consistent demographic risk factor. Gender difference is not consistently found. Prevalence and incidence vary

TABLE 83.1 Adverse Neurologic Effects of D_2 Receptor–Blocking Agents

Clinical Syndromes	Major Features
Acute dystonic reaction	Sustained twisting movements occurring within the first few days of exposure to DRBA including oculogyric crisis
Acute akathisia	Inability to sit still with motor and sensory features within a few days or weeks of DRBA treatment
Drug-induced parkinsonism	Clinical features mimicking idiopathic Parkinson disease in the setting of DRBA
Neuroleptic malignant syndrome	An idiosyncratic combination of fever, dysautonomia, and movement disorder that can be severe and fatal
Tardive Dyskinesia Syndromes	Delayed-onset abnormal involuntary movements or sensory symptoms that persist even after discontinuation of a DRBA
• Withdrawal emergent syndrome	Choreic movements in children after stopping DRBA
• Tardive dyskinesia	The classic tardive dyskinesia consisting of orobuccolingual and limb dyskinesia
• Tardive dystonia	Focal or generalized sustained twisting movements associated with chronic DRBA treatment
• Tardive akathisia	Restlessness consisting of subjective sensation of inability to sit still and stereotypic restless movements
• Tardive pain	Painful sensation that is often a focal form of tardive akathisia
• Tardive tics	Motor and vocal tics associated with chronic DRBA
• Tardive myoclonus	Lightning like jerky movements associated with chronic DRBA
• Tardive tremor	Tremor associated with chronic DRBA

Abbreviation: DRBA, dopamine receptor blocking agent.

in different regions of the world. Genetic studies have implicated variants in genes involved in drug metabolism or dopaminergic system to influence the risk of TDS. Tardive dystonia is rarer than the classic type and is more common in younger patients. Other TDS, including tardive akathisia, accounts for about 10% of all TDS.

PATHOBIOLOGY

The pathogenesis of neuroleptic-induced neurologic disorders such as parkinsonism is due to antagonization of dopamine effect at the D_2 receptors. The DRBAs that bind most tightly to the receptors are the ones most likely to induce parkinsonism and TDS. The second-generation antipsychotics are atypical in that they have less propensity to produce these complications, but most are not free of inducing these side effects. Clozapine (Clozaril), a drug that predominantly blocks the D_4 receptor and serotonin receptor subtypes, is relatively free of these complications, except for acute akathisia. The monoamine-depleting drugs, reserpine and tetrabenazine derivatives, can induce acute akathisia and drug-induced parkinsonism. Tetrabenazine has also been implicated in acute dystonic reactions and neuroleptic malignant syndrome. But none of the dopamine-depleting drugs has been convincingly implicated in causing persistent TDS. In addition, calcium channel blockers such as flunarizine and cinnarizine, and rarely selective serotonin reuptake inhibitors and lithium, produce parkinsonism and TDS, and the mechanism by which these drugs produce these complications is not known.

The pathogenesis of TDS, which can persist even after the discontinuation of the DRBAs is not well understood. Dopamine receptor upregulation occurs with the use of DRBAs, but its causality to produce TDS is not established. To explain its delayed onset and persistence, maladaptive synaptic plasticity has been proposed as an underlying mechanism. Others proposed a neurodegenerative process triggered by oxidative stress or by the drugs binding to neuromelanin with resulting internalization of the cell membrane, but all these hypotheses remain to be validated. Genetic polymorphism studies have noted association of variations of drug metabolism genes, monoamine receptors or transporters, and those associated with synaptic plasticity, but these findings need to be confirmed.

DIAGNOSIS

It is important to recognize the different phenomenologies caused by the DRBAs; each requires specific treatment.

Acute Dystonic Reaction

Acute dystonic reaction manifests as sustained, twisting movements and postures of the cranial, cervical, and other body parts. Severe sustained twisting and uncomfortable postures of limbs, trunk, neck, tongue, and face are dramatic. *Oculogyric crisis* is a form of dystonia in which the eyes are deviated conjugately in a fixed posture for minutes or hours. The diagnosis is made in the setting of recent exposure to a DRBA. Acute dystonic reaction tends to occur within the first few days of exposure to the DRBA and predominantly affects children and young adults, males more than females.

Acute Akathisia

Akathisia consists of a *subjective* sense of restlessness and the most characteristic complaint is the inability to sit still. Akathisia is associated with *motor* features of restlessness. These include frequent and repetitive stereotyped movements, such as pacing, repeatedly caressing the scalp, crossing and uncrossing the legs, and repetitive body rocking. Acute akathisia occurs within the first few days or weeks of DRBA use. It may also appear later in treatment as dosage is being increased. It can occur in subjects of any age. It is self-limiting if the offending drug is stopped.

Drug-Induced Parkinsonism

The diagnosis of drug-induced parkinsonism is based on the cardinal features of tremor at rest, bradykinesia and rigidity, plus the history of current or recently discontinuation of a neuroleptic drug.

Neuroleptic Malignant Syndrome

The neuroleptic malignant syndrome (see also Chapter 133) is a rare complication characterized by a triad of fever, signs of autonomic dysfunction (eg, pallor, diaphoresis, blood pressure instability, tachycardia, pulmonary congestion, tachypnea), and a movement disorder (usually akinesia and rigidity) with the history of recent exposure to a DRBA. The level of consciousness may be depressed with obtundation and confusion, eventually leading to stupor or coma; death may occur. Neuroleptic malignant syndrome can occur any time during DRBA treatment.

Tardive Dyskinesia Syndromes

The diagnosis of TDS depends on the recognition of a typical pattern of abnormal involuntary movements or sensory symptoms plus documented use of the offending agents. *Diagnostic and Statistical Manual of Mental Disorders* (5th ed) criteria notes at least 1 to 3 months of exposure for the diagnosis, depending on the age of the patient. The symptoms should have either started while the patient was still taking the drug or within 3 months of discontinuing the drug and persists at least 1 month after medication change or discontinuation. The timing is a continuous spectrum, however, and TDS has been noted even after a few days of DRBA exposure. The TDS is the most feared complications of antipsychotic medications because the symptoms can be long-lasting and often permanent.

Withdrawal Emergent Syndrome

Withdrawal emergent syndrome may be a mild variant of TDS. "Emergent" implies that the symptoms emerge after abrupt cessation of the chronic use of an antipsychotic drug. The syndrome is primarily one of children and persist only for a few weeks before dissipating. The abnormal movements resemble those of Sydenham chorea; they are not stereotyped and repetitive, as seen in classic TDS.

Classic Tardive Dyskinesia

Classic tardive dyskinesia consists of repetitive (stereotypic) movements. The lower part of the face is most often involved. This orobuccolingual dyskinesia resembles continual chewing movements, with the tongue intermittently darting out of the mouth. Movements of the trunk may cause a repetitive pattern of flexion and extension (body rocking). The distal parts of the limbs may show incessant flexion-extension movements.

The proximal muscles are usually spared, but respiratory dyskinesias may occur.

The classic tardive dyskinesia should be differentiated from other movement disorders affecting the face. Patients with Huntington disease show facial chorea. They are frequently treated with antipsychotic drugs; a resulting tardive dyskinesia may be superimposed on the chorea; the presence of akathisia or repetitive (stereotyped) involuntary movements suggests the additional diagnosis of tardive dyskinesia. Other differential diagnoses to be considered include chorea and stereotypies involving face from other drugs such as levodopa, anticholinergic drugs, phenytoin, antihistamines, and tricyclic antidepressants. Other neurologic disorders such as hepatocerebral degeneration and cerebellar and brainstem stroke should be considered as are the abnormal involuntary movements from edentulous malocclusion.

Several other important forms of TDS are now recognized. Unlike the classic orobuccolingual dyskinesia described earlier, these other forms can be more disabling.

Tardive Dystonia

Tardive dystonia is a chronic dystonia caused by DRBAs. Individuals of all ages are susceptible to tardive dystonia, and younger individuals are more likely to have a more severe generalized form. In older individuals, tardive dystonia is usually focal (affecting a single body part), often in the face or neck, and may remain confined to these regions or may spread to the arms and trunk. The legs are infrequently affected. Often, neck involvement consists of retrocollis and the trunk arches backward. The arms are typically rotated internally, the elbows extended, and the wrists flexed. The differential diagnosis includes all the many causes of dystonia. Oromandibular dystonia is probably the most common form of spontaneous oral dyskinesia. Often, oromandibular dystonia takes the appearance of a repetitive opening and closing of the jaw as the patient attempts to overcome the muscle pulling. To discern if the repetitive movements are volitional or spontaneous, the examiner should ask the patient not to fight the movements but to let them come out as they want to. In dystonia, there will usually be a sustained contraction, such as jaw opening or clenching. Wilson disease, in particular, must be excluded specifically in patients with psychiatric symptoms and dystonia.

Tardive Akathisia

Tardive akathisia is another important disabling variant of tardive dyskinesia. It is a chronic akathisia consisting of a subjective aversion to being still. Motor signs of restlessness include frequent, repeated, stereotyped movements, such as marching in place, crossing and uncrossing the legs, and repetitively rubbing the face or hair with the hand. Patients may make moaning sounds. Patients may not use the word "restless" to describe their symptoms, instead they may use expressions such as "going to jump out of my skin" or "jittery" or "exploding inside." In contrast to acute akathisia, the delayed type tends to become worse when antipsychotic medication is withdrawn, similar to other TDS on discontinuance of these drugs. As with other types of TDS, tardive akathisia tends to persist. Usually, tardive akathisia is associated with classic orobuccolingual dyskinesia. Classic tardive dyskinesia, tardive dystonia, and tardive akathisia may occur together. Akathisia can appear as focal discomfort, such as pain, which can be exceedingly distressing. The diagnosis of focal akathisia is challenging and is discussed further in the following text.

Other Tardive Syndromes

Less common variants of tardive dyskinesia include tardive pain, tardive tics, tardive myoclonus, and tardive tremor. Tardive pain most commonly manifests as painful or burning mouth or vagina. These may be the unpleasant symptoms of focal akathitic complaint that patients often refer to as pain. Tardive tics are rare and similar to phenomenology of chronic motor tics or Tourette syndrome. Myoclonus can occur from many different etiologies and neuroleptics may induce them as a delayed-onset tardive syndrome. Tardive tremors are distinguished from essential tremor, Parkinson disease, cerebellar tremor, and other facial tremors by its etiology. The tardive syndromes involving facial movements need to be differentiated from hemifacial spasm, myokymia, and synkinesis of facial muscles from faulty regeneration after facial nerve injury based on their difference in phenomenology.

MANAGEMENT

Efforts should be made to prevent the neuroleptic-induced complications because these are iatrogenic disorders. Antipsychotic drugs should be given only when indicated, namely, to control psychosis or a few other conditions where no other effective agent has been helpful, as in some choreic disorders or tics. These drugs should not be used indiscriminately, and when they are used, the dosage and duration should be as low and as brief as possible. If the psychosis has been controlled, the physician should attempt to reduce the dosage and even try to eliminate the drug, if possible. In nonpsychotic disorders, such as tics, other drugs should be tried first, and only if they fail should a DRBA be used.

Acute Dystonic Reaction

Acute dystonic reaction is easily reversible with parenteral administration of antihistamines (eg, diphenhydramine 50 mg intravenously), anticholinergic drugs (eg, benztropine mesylate 2 mg intramuscularly), or diazepam (5-7.5 mg intramuscularly).

Acute Akathisia

Acute akathisia disappears on discontinuance of the offending drug. Acute akathisia sometimes improves with the β-adrenergic blocker propranolol given in doses of 20 to 80 mg/d or mirtazapine (15 mg/d).

Drug-Induced Parkinsonism

Drug-induced parkinsonism has a variable response to levodopa (titrated up to 600-1,500 mg). Oral anticholinergic drugs (trihexyphenidyl 2-15 mg/d) and amantadine (up to 300 mg/d) are effective. On withdrawal of the offending antipsychotic drug, the symptoms slowly disappear in weeks or months.

Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome, a potentially lethal condition, treatment needs to be started immediately with hospitalization, initiating supportive therapy including intravenous hydration and cooling to address medical complications such as fever, rhabdomyolysis, and renal failure. The withdrawal of the antipsychotic medication is critical. Although controlled trials have

FIGURE 83.1 Treatment algorithm for tardive dyskinesia syndromes. Abbreviation: DRBAs, dopamine receptor blocking agents.

not been conducted, numerous reports suggest that dantrolene sodium, a muscle relaxant, and levodopa or direct-acting dopamine agonists, may be beneficial. Carbamazepine is also effective. In most patients, the antipsychotic medication can be restarted later without recurrence of the syndrome.

Tardive Dyskinesia Syndromes

Once TDS have appeared, the logical treatment approach calls for eliminating or reducing the dosage of the causative agents, DRBAs, especially in cases where alternative approaches are available and the indication was a short-term relief of gastrointestinal or psychiatric problems (Fig. 83.1). It is prudent to taper DRBAs slowly to avoid worsening of the original indication and TDS. Reducing the dosage or discontinuing the offending drug can worsen the disorder in the first few weeks after withdrawal or even unmask the TDS that were not noticed. Switching from the first-generation antipsychotic medication to the newer antipsychotics is also reasonable because the incidence of TDS is less with many of the newer antipsychotics, but there is no evidence that such a switch improves TDS once it started. Paradoxically, starting or increasing the dose of DRBAs can reduce TDS, by masking the movements. Because DRBAs are the offending agents, such approach is used as the last resort and temporarily. The withdrawal emergent syndrome is self-limiting but may take weeks to resolve. Reintroducing the antipsychotic drug and then slowly tapering the dosage can eliminate the choreic movements of withdrawal emergent syndrome.

If the TDS symptoms are too distressing, treatment with vesicular monoamine transporter (VMAT) inhibitors that depletes monoamines may suppress the TDS (see Table 83.2 and Fig. 83.1). Reserpine (0.75-1.5 mg/d) is a nonspecific VMAT inhibitor and tetrabenazine (25-150 mg/d) and its analogs are more selective inhibitors for VMAT2, which is present preferentially in the central nervous system, and therefore produce less side effects. Deutetrabenazine is a modified form of tetrabenazine that has slower metabolism and can be started at 6 mg twice a day and increased by 6 mg a day up to 24 mg twice a day. Most patients improve on 24 to 36 mg/d. A short-term trial up to 3 months did not show significant side effects LEVEL 1.[1,2] Valbenazine is another selective VMAT2 inhibitor that can be used at 40 to 80 mg once daily LEVEL 2.[3] Side effects of these VMAT inhibitors may consist of worsening or producing parkinsonism, depression, sedation, akathisia, dry mouth, and lowered blood pressure. The dosage should be increased gradually to minimize the side effects. Tardive dystonia may also be treated by anticholinergic drugs such as trihexyphenidyl, baclofen, or botulinum toxin injections if focal tardive dystonia is the predominant concern (see Table 83.2 and Fig. 83.1). Deep brain stimulation targeted to globus pallidus interna can be considered when medication therapy fails. For tardive akathisia, propranolol may be tried (see Table 83.2 and Fig. 83.1).

OUTCOME

Neuroleptic-induced movement disorders can be a diagnostic challenge and difficult to manage. In general, they improve with reduction or discontinuation of the neuroleptics, but TDS can persist despite discontinuation of the offending drugs. There are only a few published data on remission of TDS after complete withdrawal of DRBAs; the prevalence of the remission is surprisingly low, ranging from 2% to 13% although improvement is seen in about 20% to 30%. For those who remain on the DRBAs may also show apparent disappearance of tardive dyskinesia in up to 60% of cases, but their symptoms are likely masked by DRBAs because their improvement is often associated with worsening of parkinsonism. The best outcome we should aim for is to minimize the risk of this iatrogenic disorder by judicious use of neuroleptics.

Videos can be found in the companion e-book edition. For a full list of video legends, please see the front matter.

TABLE 83.2 Treatment Options for Tardive Dyskinesia Syndromes

Medication	Dose Range	Side Effects
Valbenazine	6-24 mg twice a day	QT prolongation, somnolence, akathisia
Deutetrabenazine	40-80 mg once daily	Depression, QT prolongation, akathisia, neuroleptic malignant syndrome, parkinsonism
Tetrabenazine	25-150 mg/d divided in three or four doses	Depression, QT prolongation, akathisia, neuroleptic malignant syndrome, parkinsonism
Reserpine	0.75-1.5 mg/d divided in three or four doses	Depression, hypotension, akathisia
Clonazepam	0.25-6 mg/d divided in three or four doses	Drowsiness, dizziness, fatigue, irritability
Amantadine	100-400 mg/d divided in three or four doses	Hallucinations, dizziness, peripheral edema, nausea
Ginkgo biloba	80-240 mg/d divided in three doses	Bleeding disorders, headache, dizziness, constipation
Deep brain stimulation	Globus pallidus interna	Infection, intracerebral hemorrhage, gait and speech disturbances, paresis, confusion
For Tardive Dystonia Only		
Trihexyphenidyl	1-40 mg/d divided in three or four doses	Blurred vision, dizziness, confusion, drowsiness, constipation, urinary retention
Baclofen	10-100 mg/d divided in three or four doses	Drowsiness, dizziness, weakness, confusion, fatigue
Botulinum toxin	Local injection	Excessive weakness of injected muscles
For Tardive Akathisia Only		
Propranolol	20-160 mg/d divided in three or four doses	Fatigue, dizziness, bradycardia, hypotension, depression

Choreas 84

Ruth H. Walker and Joseph Jankovic

KEY POINTS

1. Chorea can be due to a wide variety of causes, including pharmacologic, genetic, structural, autoimmune, and metabolic factors.
2. Sydenham disease is the most likely cause of acute-onset childhood chorea.
3. Management should be directed at the most clinically limiting symptoms of the underlying disease, which may not be the movement disorder.
4. Management of chorea primarily involves decreasing dopaminergic neurotransmission, either pre- or postsynaptically, and should be periodically tapered to evaluate efficacy.

INTRODUCTION

Chorea is a hyperkinetic movement disorder characterized by continual, jerk-like movements that flow randomly from one body part to another. Patients may be able to partially suppress the involuntary movements or "camouflage" them by incorporating them into semipurposeful activities (parakinesia). As a result of chorea, patients have difficulty maintaining a sustained voluntary contraction, such as tongue protrusion or a persistent hand grip, resulting in intermittent contractions and relaxations (milkmaid grip). Chorea should be differentiated from "pseudochoreoathetosis" due to loss of proprioception. Choreic movements can be associated with many disorders; the most common are listed in **Table 84.1**.

EPIDEMIOLOGY

Chorea is nearly always secondary to some underlying disorder. In addition to the genetic disorders, such as Huntington disease (HD) (covered elsewhere in this volume), of which it is a typical feature, chorea can be an atypical feature of other genetic disorders such as the inherited ataxias. The list of possible genetic causes of chorea continues to grow, as evolving molecular diagnostic methods identify patients with atypical phenotypes of specific genetic disorders, in addition to novel genetic etiologies.

Similarly, although chorea is a typical feature of Sydenham disease (SD), it can be variably present in the setting of other autoimmune disorders, such as systemic lupus erythematosus. A number of metabolic derangements, most commonly diabetic nonketotic hyperglycemia, can cause chorea, although why certain patients develop this, and why the symptoms are classically asymmetric, is unknown.

PATHOBIOLOGY

In terms of the direct/indirect pathway of basal ganglia functioning, chorea can be conceptualized as an overall decrease in activity of the indirect pathway. This can be a result of loss of γ-aminobutyric acid-ergic neurons projecting from the putamen to the external segment of the globus pallidus, resulting in disinhibition and increased activity of this nucleus. The increased activity of these γ-aminobutyric acid-ergic neurons inhibits the glutamatergic neurons of the subthalamic nucleus. This has an effect analogous to a lesion of this nucleus, as in hemiballismus. This decreased output may result in a loss of inhibition at the level of the thalamocortical motor pattern generator and hence breakthrough of involuntary movements.

In general, functional imaging demonstrates a hypometabolic state of the basal ganglia in neurodegenerative disorders and a hypermetabolic state in autoimmune disorders. It is intriguing that these opposite changes can result in an identical movement disorder; it is possible that the indirect pathway neurons, as described above, which bear dopaminergic D2 receptors, are more vulnerable to metabolic or neurochemical disruption than the D1 dopaminergic neurons of the direct pathway.

CAUSES OF CHOREA

Autoimmune Choreas

Sydenham Disease

SD (acute chorea, St. Vitus dance, chorea minor, rheumatic chorea) is a disease of childhood characterized by chorea, which is often asymmetric or may be unilateral (hemichorea) in about 20% of the cases (▷ **Video 84.1**). The term *Sydenham disease*, rather than *Sydenham chorea*, is preferred, as chorea is only one of many manifestations, including a variety of neurologic, psychiatric, cardiac, rheumatologic, and other problems.

SD is a consequence of infection with group A β-hemolytic *Streptococcus*, which is thought to induce antibodies that cross-react with neuronal cytoplasmic antigens on neurons of caudate and subthalamic nuclei. Unlike arthritis and carditis, which occur soon after the infection, the appearance of chorea may be delayed for 6 months or longer.

Acute chorea is almost exclusively a disease of childhood; over 80% of the cases occur in patients between the age of 5 and 15 years. Onset of the first attack after the age of 15 years is uncommon. Girls are affected more than twice as frequently as boys.

The chorea, with some exceptions, is self-limited, and fatalities are rare except as a result of cardiac complications. On average, the motor symptoms persist for 3 to 6 weeks, but the neuropsychiatric symptoms, particularly obsessive-compulsive

TABLE 84.1 Differential Diagnosis of Chorea[a]

Developmental Choreas
Physiologic chorea of infancy
Chorea minima
Idiopathic Choreas
Oral-lingual dyskinesia and edentulous orodyskinesia
Hereditary Choreas
Huntington disease
Chorea-acanthocytosis (*VPS13A* gene)
McLeod syndrome (*XK* gene)
Brain-Lung-Thyroid (*NKX2-1*) Syndrome
Other heredodegenerative disorders: Huntington disease–like disorders (eg, prion protein [*PRNP*], junctophilin-3 [*JPH3*] gene mutations), dentatorubral-pallidoluysian atrophy (*ATN1* gene mutations), spinocerebellar ataxias (SCA types 1, 2, 3, 8, 17), *C9orf72* expansions, ataxia-telangiectasia, ataxia with oculomotor apraxia type 1 (aprataxin gene), ataxia with oculomotor apraxia type 2 (due to mutations in the senataxin gene), ADCY5 disease and other paroxysmal dyskinesias, tuberous sclerosis of basal ganglia, phospholipase-associated neurodegeneration (*PLA2G6* mutations), neuroferritinopathy, aceruloplasminemia, other neurodegenerations with brain iron accumulation, Wilson disease, infantile bilateral necrosis
Neurometabolic Disorders
Lesch-Nyhan syndrome, lysosomal storage disorders, amino acid disorders, Leigh disease, porphyria
Drugs
Neuroleptics (tardive dyskinesia, withdrawal emergent syndrome), dopaminergic drugs, anticholinergics, amphetamines, cocaine, tricyclics, oral contraceptives
Toxins
Alcohol intoxication and withdrawal, anoxia, carbon monoxide, manganese, mercury, thallium, toluene
Metabolic and Endocrine Disorders
Hypernatremia, hyponatremia, hypomagnesemia, hypocalcemia, hypoglycemia, hyperglycemia (nonketotic diabetic)
Pregnancy (*chorea gravidarum*—likely due to recrudescence of Sydenham disease)
Acquired hepatocerebral degeneration
Renal failure
Nutritional (eg, ketogenic diet, beriberi, pellagra, vitamin B_{12} deficiency, particularly in infants)
Infectious and Postinfectious
Sydenham disease
Encephalitis lethargica
Various other infectious and postinfectious encephalitis, Creutzfeldt-Jakob disease
Immunologic
Systemic lupus erythematosus, antiphospholipid syndrome, *chorea gravidarum*
Henoch-Schönlein purpura
NMDA antibody (and other autoantibodies) encephalitis
HIV infection
Vascular/Structural
Infarction or hemorrhage
Arteriovenous malformation, moyamoya disease
Polycythemia rubra vera
Antiphospholipid syndrome
Migraine
Following cardiac surgery with hypothermia and extracorporeal circulation in children (choreoathetosis and orofacial dyskinesia, hypotonia, and pseudobulbar signs or CHAP syndrome)
Intracranial hypotension due to cerebrospinal fluid leak
Tumors
Trauma
Other Secondary Choreas
Cerebral palsy (anoxic), kernicterus, sarcoidosis, toxoplasmosis, multiple sclerosis, Behçet disease, polyarteritis nodosa, mitochondrial disorders

Abbreviation: NMDA, *N*-methyl-D-aspartate.
[a]Modified from Fahn S, Jankovic J. *Principles and Practice of Movement Disorders*. Philadelphia, PA: Churchill Livingstone/Elsevier; 2007.

behavior, may persist for months to years, recur, or even be lifelong. After spontaneous remission, some female patients have a recurrence during pregnancy, so-called *chorea gravidarum*, or with the use of oral contraceptives or hormone replacement therapy.

SD is associated with a variety of neurobehavioral problems, such as irritability, emotional lability, anxiety, obsessive-compulsive behavior, and other psychiatric manifestations. Speech impairment can occur, and, more rarely, encephalopathy, reflex changes, weakness, gait disturbance, headache, seizures, and cranial neuropathy.

The diagnosis is made without difficulty from the appearance of the acute or subacute onset of characteristic choreic movements in a child with relatively recent history of streptococcal infection. Although serum antistreptolysin O and anti-DNase B titers are elevated in less than 30% of cases, these tests have a high specificity. Neuroimaging is typically normal but may show enlargement of the striatum and globus pallidus.

When the severity of the movements interferes with proper rest, dopamine-depleting drugs or a short course of dopamine receptor-blocking drugs may be considered. Other drugs, such as benzodiazepines, valproate, or carbamazepine, may be also effective. If the syndrome is debilitating, for example, in the severely hypotonic form, immunosuppressive therapies, such as corticosteroids, intravenous immunoglobulin, or plasmapheresis, may be required. Treatment of the precipitating streptococcal infection generally consists of a full 10-day course of oral penicillin V therapy or an injection of benzathine penicillin G. Prophylactic administration of penicillin for at least 10 years is recommended to prevent other manifestations of rheumatic fever, of which SD may be its sole manifestation.

Systemic Lupus Erythematosus

Chorea in systemic lupus erythematosus, often fluctuating and intermittent, has been associated with the presence of serum antiphospholipid antibodies (lupus anticoagulant), a heteroge-

neous group of antibodies that can cause platelet dysfunction and result in thrombosis. Treatment is directed at the immunologic features of the disorder and anticoagulation.

Antiphospholipid Antibody Syndrome

Primary antiphospholipid antibody syndrome also causes chorea, particularly in young women. Systemically, patients may have migraine, spontaneous abortions, venous and arterial thromboses, thickened cardiac valves, livedo reticularis, and Raynaud phenomenon. The central nervous system is involved with strokes, multi-infarct dementia, and chorea. Activated partial thromboplastin time is prolonged due to the presence of lupus anticoagulant, and there are high titers of anticardiolipin antibodies exist. Anticoagulation, immunosuppressive drugs, and plasmapheresis have had variable success; it is difficult to interpret the effectiveness of therapeutic interventions because spontaneous remission occurs frequently.

Chorea due to Other Autoantibodies

Chorea associated with anti–*N*-methyl-D-aspartate (NMDA) receptor encephalitis is particularly important to recognize because there is the potential for good outcomes with appropriate therapies. Often presenting as a subacute neuropsychiatric disorder, anti-NMDA encephalitis is characterized by a variety of movement disorders including chorea, stereotypy, dystonia, and myorhythmia. A search for ovarian teratoma or other benign tumors should be initiated because their removal is a critical part of the treatment. Immunoglobulin G antibodies against the NR1 subunit of the NMDA receptor are often identified.

Other autoantibodies, either as paraneoplastic or idiopathic autoimmune disorders, may cause chorea. If total body imaging does not reveal a neoplasm which can be surgically removed, immunosuppressive therapies should be employed. Aggressive and persistent immunosuppressive management is critical and can result in good outcomes despite a prolonged disease course. The list of causative autoantibodies continues to expand but includes anti-LGI1, anti-CV2/CRMP5, anti-Ma, and others.

Structural and Vascular Chorea and Ballism

Choreic movements confined to the arm and leg on one side of the body (hemichorea, hemiballism) may develop abruptly in middle-aged or elderly patients. Ballistic movements are a more violent form of chorea and are characterized by large amplitude uncoordinated activity of the proximal appendicular muscles, so vigorous that the limbs are forcefully and aimlessly thrown about. Padding of the limbs or bed side rails may be necessary to prevent injury. The movements are present at rest and may be suppressed during voluntary limb movement.

Sudden onset of chorea suggests a vascular basis; indeed, it may be preceded by hemiplegia or hemiparesis. In such instances, the choreic or ballistic movements appear when motor function returns. This type of movement disorder may be the result of a destructive lesion of the contralateral putamen, subthalamic nucleus or their connections. Vascular lesions, hemorrhagic or occlusive in nature, are the most common cause, but hemiballism has been found in association with structural lesions, for example, due to toxoplasmosis in immunocompromised patients, tumors, and multiple sclerosis. In general, the movements tend to diminish over time, but they may be persistent and require therapeutic intervention. The agents noted elsewhere in this chapter for the control of choreic movements in general have proved effective.

Asymmetric chorea-ballism may be a feature of diabetic hyperosmolar hyperglycemic nonketotic syndrome. The characteristic magnetic resonance imaging (MRI) finding is high signal in the contralateral putamen on T1 sequences. Older women, especially those of East Asian ancestry, appear to be most vulnerable to this condition. The underlying pathophysiology is unclear. The symptoms typically resolve as the metabolic abnormalities are corrected; however, the improvement may be delayed for weeks or months and in rare cases is persistent.

Choreoathetosis as a sequela to surgery for congenital heart disease appears to be associated with prolonged time on pump, deep hypothermia, and circulatory arrest. The incidence is decreasing most likely due to technologic improvements.

Occasionally, chorea can be due to intracranial hypotension due to spontaneous cerebrospinal fluid leaks. The mechanism is unknown but is likely due to disruption of basal ganglia pathways due to structural shifts.

Genetic Causes of Chorea

Autosomal Recessive

Chorea-acanthocytosis

Chorea-acanthocytosis (ChAc) is one of the neuroacanthocytosis syndromes and is also, somewhat confusingly, often referred to as "neuroacanthocytosis." The ChAc is due to autosomal recessive mutations of the gene *VPS13A* on 9q21.2, which codes for the protein chorein. The chorea is typically less prominent than that seen in HD but occasionally can be just as severe. In addition to chorea, patients with ChAc often have tics, seizures, parkinsonism, cognitive decline, amyotrophy, dysphagia, absent tendon reflexes, feeding dystonia (the tongue pushes food out of the mouth), and self-mutilation with lip and tongue biting. Age at onset is typically in late adolescence and young adulthood but occasionally may be later. The diagnosis is supported by finding more than 10% spiky erythrocytes (acanthocytes) in blood smears, although this is not an invariable feature. Detection of acanthocytes can be enhanced if a wet smear of blood is diluted 1:1 with normal saline (Fig. 84.1). Occasionally, electron microscopy is needed to confirm the presence of acanthocytes. The diagnosis can be made by Western blot to determine the absence of chorein and by identification of mutations of the affected gene (Fig. 84.2). Elevated creatine kinase, and sometimes liver enzymes, strongly supports the diagnosis in the presence of typical clinical features.

Positron emission tomography scan typically shows hypometabolism in the caudate nucleus as well as reduced fluorodopa uptake and decreased dopamine receptor binding in the striatum.

The Autosomal Recessive Ataxias

Chorea can be a feature of several of the autosomal recessive ataxias, specifically ataxia-telangiectasia (AT), ataxia with oculomotor apraxia (AOA) types 1 and 2, and Friedreich ataxia. These typically present in childhood, although occasionally develop later. Serologic findings such as elevated α-fetoprotein and hypoalbuminemia can be informative in AT and the AOAs.

X Linked

McLeod Syndrome

McLeod syndrome has historically been known as an X-linked form of neuroacanthocytosis. It is due to mutations of the *XK*

FIGURE 84.1 Acanthocytes in a patient with chorea-acanthocytosis.

gene on Xp21. Besides allelic variants of the *XK* gene, McLeod syndrome may be part of a contiguous gene deletion syndrome involving *XK* and adjacent genes, including those for chronic granulomatous disease, Duchenne muscular dystrophy, and retinitis pigmentosa. The affected protein, XK, typically expresses an antigen, known as Kx on the surface of erythrocytes. When XK is abnormal, due to the genetic mutation, expression of the Kx antigen is absent. There is also reduced expression of the antigens of the Kell protein, which is covalently linked to XK in the erythrocyte membrane; this antigen presentation is known as the "McLeod phenotype" and has implications for blood transfusion.

McLeod syndrome typically presents in middle-aged men, although, rarely, heterozygous carrier females can be affected. The clinical features are very similar to ChAc, with chorea, dystonia, tics, parkinsonism, seizures, neuropathy, cognitive decline, and psychiatric symptoms. Feeding dystonia and self-mutilation are not usually seen. Similar to ChAc, the presence of acanthocytosis is informative, when present, but elevated creatine kinase and liver enzyme levels may be more useful in making the diagnosis. Distinct features of McLeod syndrome are cardiomyopathy and dysrhythmia, which are potentially treatable causes of morbidity and mortality.

Autosomal Dominant

The most common cause of autosomal dominant chorea is HD (covered elsewhere in this volume). In this chapter, we briefly mention other forms of autosomal dominant chorea.

C9orf72 Disease

Mutations of *C9orf72* can cause a spectrum of neurologic symptoms, including frontotemporal dementia, motor neuron disease, and an HD-like phenotype. The mutation is an expansion of a hexanucleotide repeat of 9p21.2 and after HD is one of the most common causes of genetic chorea in non-African populations. Hyperreflexia and signs of frontal lobe dysfunction suggest the diagnosis.

The Spinocerebellar Ataxias

Although labeled as a spinocerebellar degeneration, several of the spinocerebellar ataxias (SCAs) can present with a choreic

FIGURE 84.2 Absence of chorein in patient (*155a*) with chorea-acanthocytosis (Western blot). (Courtesy Dr. Benedikt Bader, Munich, Germany.)

phenotype, including SCA types 1, 2, 3, 8, and 17 (which has also been reported as "HDL4"). There does not appear to be a correlation between the size of the trinucleotide repeat expansion and the clinical presentation. A variety of movement disorders, including parkinsonism and dystonia, in addition to chorea, can be seen.

Dentatorubral-Pallidoluysian Atrophy

Once thought to be found only in the Japanese population, this autosomal dominant disorder is now known to be more widespread, thanks to discovery of expanded cytosine-adenine-guanine (CAG) repeats in the dentatorubral-pallidoluysian atrophy gene (*DRPLA* or *ATN1*) on chromosome 12p13.31 that codes for the atrophin-1 protein, which is phosphorylated by c-Jun NH-terminal kinase. The abnormal polyQ protein has reduced affinity for c-Jun NH-terminal kinase. Also called the *Haw River syndrome* because of its occurrence in some African Americans in North Carolina, DRPLA clinically overlaps with HD and manifests combinations of chorea, myoclonus, seizures, ataxia, and dementia. The phenotype varies according to triplet (CAG) repeat length, and anticipation and excess of paternal inheritance in younger onset cases with longer repeat lengths are seen. The neuropathologic spectrum is centered around the cerebellofugal and pallidofugal systems, but neurodegenerative changes can be found in many nuclei. In contrast to HD, DRPLA is typically associated with white matter degeneration.

Huntington Disease–like 1

Huntington disease–like 1 is an autosomal dominant disorder mapped to the prion protein gene (*PRNP*) on chromosome 20p with eight extra octapeptide repeats in the prion protein. The time course of the disease, over decades, is more suggestive of HD than of a prion disorder. Presentation is typically in young adulthood; symptoms can be variable, even within a single family, and can include ataxia, in addition to features suggestive of HD. Neuroimaging tends to show generalized brain atrophy; abnormal discharges such as triphasic waves are typically found on electroencephalography.

Huntington Disease–like 2

The autosomal dominant Huntington disease–like 2 appears to be present exclusively in individuals of African ancestry. It is due to cytosine-thymine-guanine and CAG repeat expansions of the gene on chromosome 16q24.2, encoding junctophilin-3, a protein of the junctional complex linking the plasma membrane, and the endoplasmic reticulum. Clinical, radiologic, and neuropathologic features strongly resemble those seen in HD. Subtle changes in thalamic volumes can be detected using volumetric methods, but otherwise, Huntington disease–like 2 is clinically indistinguishable from HD.

Brain-Lung-Thyroid (*NKX2-1*) Syndrome

This childhood-onset, choreic disorder has been previously considered to be relatively benign and nonprogressive, but the phenotype has been expanding since the discovery of mutations in the *NKX2-1* (previously called *TITF1*) gene on chromosome 14q13.3, coding for a transcription factor essential for the organogenesis of the lung, thyroid, and basal ganglia. This autosomal dominant syndrome has been also described in patients with deletion of not only the *NKX2-1* gene but also the contiguous *PAX9* gene. These mutations should be considered in children and adults with chorea, motor delay, short stature, gait ataxia, dystonia, myoclonus, tics, intellectual impairment, congenital hypothyroidism, and chronic lung disease. The term *brain-lung-thyroid syndrome* has been used to draw attention to the multiorgan involvement in this condition and rather than employing the misleading designation of "benign hereditary chorea."

Brain MRI has been generally reported to be unremarkable, but some cases showed hypoplastic pallida, lack of differentiation of medial and lateral components, and bilateral signal hyperintensities on T2-weighted MRI images. About half of the patients spontaneously improve in adulthood.

Other Choreas

There are many other genetic causes of chorea. For example, mutations in the *ADCY5* gene that codes for adenylate cyclase 5, a striatal-specific enzyme that converts adenosine triphosphate into cyclic adenosine monophosphate, have been increasingly recognized as a cause of a multisymptomatic disorder. The manifestations may include a combination of initially paroxysmal and subsequently progressive dystonia, chorea, myoclonus, spasticity in the legs, and hypotonia (in the neck and trunk). The course is often fluctuating with episodic exacerbations observed upon awakening, triggered by sleep, intercurrent illnesses, excitement, or stress. Many attacks represent medial frontal lobe seizures. Often misdiagnosed as cerebral palsy, additional features include language delay, "myopathic facial appearance," and heart failure.

Dyskinetic cerebral palsy, manifested by a combination of chorea and athetosis (choreoathetosis) and a variety of other neurologic abnormalities, including intellectual impairment, seizures, dystonia, ataxia, and spasticity, is one of the most common causes of childhood-onset chorea. This condition is usually attributed to damage in the developing fetal or infant brain, such as perinatal hypoxia-ischemia, intracranial hemorrhage or cerebral infarction, neonatal hyperbilirubinemia (Fig. 84.3), and brain maldevelopment. Cerebral palsy is the most frequent cause of disability in early childhood, with the prevalence estimated to be 1.7 to 3.1 per 1,000 live births. Although cerebral palsy is usually attributed to perinatal injury, there is a growing number of metabolic and genetic disorders that may mimic this condition.

Other common causes of chorea are drug-induced dyskinesia, such as levodopa-induced dyskinesia and tardive dyskinesia. It should also be noted that chorea may be a manifestation in many forms of paroxysmal dyskinesias. Finally, patients with functional (psychogenic) movement disorders, most typically manifested by tremor and dystonia, may rarely also exhibit features of chorea, athetosis, or ballism.

It is beyond the scope of this review to describe all causes of choreas, but the reader is directed to Table 84.1 and "Suggested Readings" section for less common forms of choreic disorders.

DIAGNOSIS

The diagnosis of chorea is based on the presence of characteristic phenomenology, and the search for etiology is guided by the following factors: the presence or absence of a family history of a similar disorder, concurrent medical conditions, current and previous medication history, time course and exacerbating/relieving factors, and other clinical and neurologic signs and symptoms. Evaluation of the patient with chorea typically

FIGURE 84.3 Magnetic resonance imaging of an 11-year-old boy with kernicterus. The T2-weighted image shows abnormal pallidal signal *(arrows)*. See also Video 84.2.

requires neuroimaging, ideally brain MRI; testing of peripheral blood for metabolic (eg, thyroid function tests) and autoimmune (eg, autoantibodies) abnormalities and for specific protein markers (eg, ceruloplasmin in Wilson disease, α-fetoprotein in AT and AOA type 2, chorein in ChAc); and, in some cases, cerebrospinal fluid analysis (eg, autoantibodies, 14-3-3 protein, cell count). Targeted genetic testing, specifically for HD, may be considered relatively early in the diagnostic process, especially if there is a suggestive family history.

Ancillary informative evaluations may include electroencephalography (which can be abnormal in prion diseases and neuroacanthocytosis syndromes) and electrophysiologic examination of nerve and muscle function (which can be abnormal in some of the degenerative cerebellar disorders and neuroacanthocytosis syndromes).

MANAGEMENT

Treatment of chorea should focus on identification of specific and potentially reversible causes, such as medications, infectious, autoimmune, or paraneoplastic etiologies. Symptomatic relief of chorea is similar to that in patients with HD and typically involves the use of medications which reduce dopaminergic neurotransmission. Dopamine receptor blocking agents such as the typical or atypical antipsychotic agents can be used; it is preferable to avoid, or at least minimize, the use of either of these agents, but especially the typical antipsychotics, due to the risk of inducing tardive dyskinesia. Of the atypical antipsychotic agents, quetiapine is probably the least likely to cause this long-term side effect; if quetiapine is not tolerated due to sedation or metabolic syndrome, clozapine is the best option, if practical.

There is level 1 evidence to support the efficacy and safety of tetrabenazine LEVEL 1[1] and deutetrabenazine LEVEL 1,[2] both causing presynaptic dopamine depletion by blocking the vesicular monoamine transporter type 2, in the treatment of chorea associated with HD, an indication approved by the U.S. Food and Drug Administration. These two drugs have been found to be useful therapeutic options for a large range of hyperkinetic movement disorders. Deutetrabenazine has additionally been approved by the U.S. Food and Drug Administration only for the treatment of tardive dyskinesia. Medications should be periodically tapered to determine if they are continuing to be therapeutically beneficial, as symptoms may resolve or evolve over time. For example, if the patient becomes parkinsonian, this might be due to medication or to disease progression. Especially in the progressive neurodegenerative syndromes, behavioral, psychiatric, cognitive, and nonmotor symptoms, such as dysphagia, can be more disabling than the movement disorder and can require multidisciplinary management. If chronic and disabling, deep brain stimulation of the internal segment of the globus pallidus may be considered; however, this option is probably best suited to nonprogressive conditions, such as chorea due to structural lesions, rather than neurodegenerative disorders such as HD.

OUTCOME

Chorea secondary to structural lesions, autoimmune, or metabolic disturbances tends to resolve over time. As a symptom of neurodegenerative disorders such as HD or ChAc, it may also resolve and be replaced by a bradykinetic, parkinsonian phenotype.

Huntington Disease 85

Karen S. Marder and Richard A. Hickman

KEY POINTS

1. Huntington disease (HD) is an autosomal dominant disorder caused by a cytosine-adenine-guanine (CAG) polyglutamine expansion in exon 1 of the Huntington gene on chromosome 4p16.3.
2. Age of onset, defined by an extrapyramidal movement disorder, is inversely related to CAG repeat length.
3. Forty or more CAG repeats will develop HD; 36 to 39 repeats: incomplete penetrance; 27 to 35 repeats: meiotic instability. Juvenile HD usually have more than 50 CAG repeats.
4. Neurodegeneration of the neostriatum and intracellular aggregation of mutant Huntingtin protein are pathologic hallmarks of Huntington disease.
5. Cognitive and psychiatric signs may occur 10 to 15 years before motor onset. The primary motor feature is chorea.
6. Treatment is symptomatic. There are no approved disease-modifying therapies.

INTRODUCTION

Huntington disease (HD) is an autosomal dominant neurodegenerative disorder caused by a cytosine-adenine-guanine (CAG) polyglutamine repeat expansion in exon 1 of the Huntington (*HTT*) gene on chromosome 4p16.3. The age of onset, defined based on the presence of a characteristic extrapyramidal movement disorder, is inversely related to CAG repeat length such that higher CAG repeat length is associated with earlier age at onset. HD is characterized by a triad of symptoms and signs including motor, cognitive, and psychiatric manifestations. Studies of premanifest HD have demonstrated changes in imaging biomarkers (putamen and caudate) that predate onset of motor signs more than 15 years prior to onset and cognitive changes that occur 10 years prior to motor onset. Symptomatic treatment for chorea is currently available; however, disease-modifying agents are not. The development of imaging, biofluid, and quantitative cognitive and motor testing will facilitate clinical trial development in both symptomatic and prodromal HD.

EPIDEMIOLOGY

George Huntington provided the classical description of the disease and its inheritance pattern in 1872. An analysis of 82 prevalence studies from 1930 to 2015 revealed a 10-fold difference in prevalence worldwide, with consistently higher prevalence in the United Kingdom (6.68 per 100,000; [95% confidence interval, 6.40-6.97]) and North America 7.33 (95% confidence interval, 6.94-7.4) compared to far lower prevalence among Asians (Hong Kong, Japan, South Korea, Taiwan) 0.4 per 100,000 (95% confidence interval, 0.36-0.44) and Black Africans (0.02 per 100,000 in South Africa). The prevalence of HD has increased 15% to 20% per decade between 1954 and 1996 despite stable incidence rates. Prevalence of HD among men and women is similar within each population. One reason for the increase in prevalence may be the application of genetic testing for diagnosis. Worldwide, the incidence of HD has ranged from 0 to 8 per million person years and has remained unchanged in the past three decades, with incidence much lower in Asia compared to those of European ancestry. Seven common haplotypes have been identified in the *HTT* gene, with a single ancestral haplotype accounting for 50% of all European chromosomes, supporting the theory that HD may have originated in Northern Europe and spread worldwide. Specific haplotypes may be more or less likely to be associated with CAG repeat expansion, which may also explain the heterogeneity of age at onset among populations.

PATHOBIOLOGY

Genetics

Age of onset of HD, defined by the presence of extrapyramidal motor signs, occurs most often between 40 and 50 years (mean age 45 y); however, cases have been reported as young as age 2 years and as old as 87 years. Between 5% and 10% develop HD before age 20 years (juvenile HD) and about 10% after 60 years. CAG repeat length is inversely correlated with age at onset and accounts for 50% to 70% of the variance in age at onset. Repeat lengths of 26 or less are normal. Repeats between 27 and 35 are considered intermediate or "high normal" and represent 3% to 5% of all "normal" alleles. Although carriers of 27 to 35 repeats will not develop manifest HD, this range confers meiotic instability, and parents, especially fathers, may transmit CAG repeats that are within the HD range to their children. Carriers of 27 to 35 repeats may evidence subtle behavioral changes, an "endophenotype," although they do not have motor or cognitive impairment. Repeats between 36 and 39 are associated with incomplete or reduced penetrance, meaning that some individuals will develop HD, generally late onset, and others will not. Diagnosis of HD in the 36 to 39 repeat range may be difficult due to confounding with age-associated signs. Individuals with 40 or more repeats will develop HD (fully penetrant) if they live long enough. Most individuals with HD have between 40 and 50 repeats. Those with juvenile HD usually have greater than 50 repeats, although greater than 100 repeats have been reported (**Table 85.1**).

There is a greater chance for CAG expansion in sperm than in ova, which explains the concept of "genetic anticipation," an earlier age at onset in the next generation. Mothers with HD pass

TABLE 85.1 CAG Repeat Ranges

Category	CAG Repeat Range	Phenotype	Additional Comments
Normal allele	≤26	Normal	
Mutable normal allele	27-35	Normal	3%-5% of all "normal" alleles May have subtle behavioral signs (endophenotype)
HD allele with reduced penetrance	36-39	Normal or HD (late onset)	0.26% of European populations May develop HD if the individual lives long enough
HD allele	≥40 repeats	HD	Repeat lengths greater than 50 associated with juvenile HD

Abbreviations: CAG, cytosine-adenine-guanine; HD, Huntington disease.

on approximately the same number of repeats (±3), whereas fathers with HD, because of meiotic instability, often pass on a higher CAG repeat length. Ninety percent of juvenile HD cases have inherited the disease from their fathers. Despite the inverse correlation of CAG repeat length with age at onset, there is significant variability of age of onset of HD even among individuals with the same CAG repeat length. Recent studies of genetic modifiers have identified a locus on chromosome 15 that delays onset by 6.1 years, a second on chromosome 15 that delays onset by 1.4 years, and a single nucleotide polymorphism (SNP) on chromosome 8 that is associated with earlier onset disease (1.6 y). In an analysis of progression of clinical and imaging data using genome-wide association, an SNP in MSH3 on chromosome 5 was associated with slower clinical progression.

Neuropathology

Neuronal loss begins in the neostriatum (caudate nucleus and putamen). A five-point grading system that ranges from 0 (no pathology) to grade 4 is based on macroscopic and microscopic criteria, which correlates with the Shoulson-Fahn Total Functional Capacity scale (Fig. 85.1). The earliest macroscopic changes are seen in the tail of the caudate nucleus. Over time, the disease appears to progress within the neostriatum in a caudorostral, medial-lateral, and dorsal-to-ventral direction with progressive involvement of the caudate nucleus and putamen. Fifty percent of neurons are lost in the caudate nucleus in grade 1, whereas 95% are lost in grade 4. Astrocytosis is associated with areas of neuronal loss and increases steadily from grades 2 to 4, with severe gliosis in stage 4. Although neuronal loss of the γ-aminobutyric acid (GABA)ergic medium spiny neurons in the neostriatum is the hallmark of HD, HD is a diffuse disease of the central nervous system with varying regional vulnerabilities. For instance, the

FIGURE 85.1 Gradations of Huntington disease (HD) pathology. Neuropathologic gradations of HD using a 5-point scale (0-4). **A-D:** Coronal sections passing through the nucleus accumbens including the head of the caudate nucleus and putamen. **A'-D':** Coronal sections passing through the globus pallidus including the putamen and caudal segment of the head of the caudate nucleus. **A,A':** Neuropathologic grade of severity 1 (HD1) (about 5% of all HD brains): There is minimal detectable change on gross examination at the sites shown in A and A'; however, the body and tail of the caudate nucleus are atrophic. **B,B':** Neuropathologic grade of severity 2 (HD2) (about 15% of HD brains): The volume loss of the neostriatum is moderate with relative preservation of its shape. **B:** The medial outline of the head of the caudate nucleus is only slightly convex, but it still bulges into the lateral ventricle. **B':** The medial edge of the lenticular nucleus lost its medial convexity. **C,C':** Neuropathologic grade of severity 3 (HD3) (about 50% of HD brains): The medial outline of the head of the caudate nucleus forms a straight line or is slightly concave medially **(C)**. **C':** The volume loss of the lenticular nucleus (putamen and globus pallidus) is discrete, and its medial outline is parallel to the anterior limb of internal capsule or is slightly concave medially. **D,D':** Neuropathologic grade of severity 4 (HD4) (about 30% of HD brains): The striatum is severely atrophic. **D:** The medial contour of the head of the caudate nucleus is concave, as is the anterior limb of internal capsule. (Courtesy of JP Vonsattel, MD.)

FIGURE 85.2 Photomicrographs of the head of the caudate nucleus **(B,C)** and the prefrontal neocortex in HD **(D,E)** and of the head of the caudate nucleus of a control brain **(A)**. **A,B:** The cellularity of the caudate nucleus is markedly increased in Huntington disease (B with an increased density of oligodendrocytes and a prominent astrocytosis). **C:** Photomicrographs of p62 immunostained sections of the head of the caudate nucleus demonstrates intranuclear inclusions (*closed arrow*; magnified further in inset C'). The neocortex also harbors abnormal protein inclusions. **D,E:** Double immunolabeling of p62 (red chromagen) and Huntingtin (HTT; brown chromagen) is shown in the prefrontal neocortex (Brodmann area 9). Both intranuclear (D, *open arrow*; further magnified in D') HTT aggregates and extranuclear HTT aggregates are seen. A dystrophic p62+/HTT- neurite is also apparent in D (*closed arrow*). E: An extranuclear HTT aggregate is enwrapped by p62 (*closed arrow*; E'). Scale bars: **A,B:** 100 μm; **C-E:** 10 μm.

nucleus accumbens is relatively resistant and neurodegeneration is seen in the later stages of the disease course. Extrastriatal involvement (subthalamic nucleus, substantia nigra pars reticulata, thalamus, brainstem, cerebellum, and neocortex) does occur, although the neurodegeneration is typically less severe than that seen in the neostriatum (see **Fig. 85.1**). Huntingtin aggregates have also been recently reported in the cervical and lumbar segments of the spinal cord of HD patients.

Microscopically, there is neuronal loss and gliosis within the caudate nucleus and putamen (**Fig. 85.2B**). A subset of neurons harbor abnormal protein inclusions that label with antibodies against ubiquitin and p62 (**Fig. 85.2C-E**). Both of these proteins are important for the intracellular degradation of misfolded proteins and within a large subset of these inclusions, Huntingtin protein (HTT) may be seen by immunohistochemistry (see **Fig. 85.2E**). Exactly how Huntingtin protein accumulates within neurons of HD patients is unclear, although experimental mouse studies have suggested that impairments in autophagy may play a role. HTT is ubiquitously expressed within the body and has been proposed to function as a scaffold for a wide variety of cellular events, ranging from gene transcription to vesicular trafficking. Because the *HTT* gene encodes for the HTT protein, the neuropathology of HD is believed to arise primarily from a toxic gain of function from an abnormal conformation of mutant HTT; however, partial loss of function of HTT and toxicity from RNA may also contribute.

Knockout and knockdown murine models have provided compelling evidence that HTT is necessary for early embryonic development. However, despite an abundance of neurodevelopmental work in murine models and cell culture systems, developmental abnormalities in the human HD brain are not clearly defined. There is a small body of evidence that suggests that children with presymptomatic HD have smaller head circumferences, and male patients tend to have smaller intracranial volumes than age-matched controls. Further work in human neuropathology is needed to explore the neurodevelopmental aspects of HD on the brain.

Neurochemistry

Up to 95% of the GABAergic medium spiny neurons that project to the globus pallidus and the substantia nigra are lost, whereas large cholinergic interneurons are selectively spared. Loss of the medium spiny neurons may be due to excessive stimulation of excitatory amino acid receptors, especially *N*-methyl-D-aspartate receptors. Although dopamine, glutamate, and GABA are thought to be most affected in HD and have been targets for therapy, multiple neurotransmitters and their receptors are involved.

Cannabinoid and adenosine A2a receptor binding in the striatum and globus pallidus externa are affected early. There is typically loss of dopamine D_1 receptors in the striatum as well as cannabinoid and D_1 receptors in the substantia nigra as the disease progresses. Loss of substance P/dynorphin neurons occurs in the late stages and correlates clinically with dystonia.

DIAGNOSIS

Diagnosis is based on the unequivocal presence of an extrapyramidal movement disorder in the setting an expanded CAG repeat or a family history of HD based on autopsy or a close family member who has undergone genetic testing. The differential diagnosis of chorea is presented in Chapter 84.

Individuals from confirmed HD families who present with signs and symptoms of HD should undergo a careful history and physical examination. As in sporadic cases, there should be consideration of causes of chorea including thyroid function tests, vitamin B_{12}, antinuclear antibody, antistreptolysin O, and human immunodeficiency virus. Because HD is the most likely etiology of the extrapyramidal movement disorder in a family with documented HD, genetic testing for the expanded CAG repeat is a more cost-effective approach. It is essential that any individual (symptomatic or presymptomatic) who is considering genetic testing be offered genetic counseling performed according to published guidelines. A center specialized in HD with a team of professionals including a neurologist, psychiatrist, and a genetic counselor is preferable.

Differential Diagnosis

From 1% to 12.4% of individuals with a clinical presentation of HD test negative for the HD gene mutation and are known as *phenocopies*. The etiology of phenocopies is heterogeneous, and often, there are clues based on ethnicity and clinical features. C9orf72 hexanucleotide repeat expansions, usually associated with amyotrophic lateral sclerosis and frontotemporal dementia may be the most common HD phenocopy, followed by SCA17, associated with triplet repeat expansions in the TATA box binding protein. Huntington disease-like 2 (HDL2) caused by a mutation in Junctophilin-3 (JPH3), which is located on chromosome 16q24.3, is associated with African or Middle Eastern ancestry and dentatorubral-pallidoluysian atrophy caused by a mutation in *ATN1* has been primarily described among Japanese. These are reviewed in Chapter 84 along with a more complete differential diagnosis of chorea.

If there is no family history of HD, a careful medication history including dopamine antagonist exposure resulting in tardive dyskinesia, use of oral contraceptives, or antiepileptic medications (phenytoin, carbamazepine, gabapentin), all of which can be associated with chorea, should be sought. Cocaine and amphetamines may also cause chorea. Additional tests would include glucose (hyperglycemia), complete blood count (polycythemia vera), thyroid function tests (hyperthyroidism), vitamin B_{12}, a sedimentation rate (to evaluate autoimmune disorders such as Sydenham chorea or lupus), ceruloplasmin (for Wilson disease), and paraneoplastic panel. Nonpaternity may also be an explanation for lack of a family history of HD.

In individuals with HD, routine studies of blood, urine, and cerebrospinal fluid (CSF) are normal. Structural magnetic resonance imaging (MRI) may show enlargement of the lateral ventricles due to atrophy of the caudate and putamen, but this may not be apparent early in the disease (**Fig. 85.3**). In a longitudinal study PREDICT-HD, mean striatal volume decline was faster in premanifest (prior to motor onset) and manifest HD compared to age-matched controls and was seen 10 years before diagnosis of "phenoconversion," defined as the emergence of the unequivocal motor signs associated with HD.

Clinical Manifestations

The triad of symptoms and signs associated with HD is an extrapyramidal movement disorder, cognitive impairment, and behavioral impairment (**Table 85.2**). Any one of the triad may

FIGURE 85.3 7T MP2RAGE images at 0.65-mm resolution showing striatal volume loss and brain shrinkage in other regions in prodromal Huntington disease (HD) (**right**, 38-y-old woman, 6.5 y to predicted onset vs control; **left**, 38-y-old woman). (Courtesy of Christopher A. Ross, MD, PhD, and Jun Hua, PhD.)

TABLE 85.2 Clinical Manifestations of Huntington Disease[a]

Clinical Domain	Signs
Motor	Involuntary movements • Chorea, dystonia, dysphagia, dysarthria Voluntary movements • Slow saccade initiation and interrupted pursuit • Finger tapping/pronation supination, gait, and balance
Cognitive	Processing speed, executive function, visuospatial perception, episodic memory, smell identification
Psychiatric	Irritability, obsessive-compulsive symptoms, perseverative behavior, depression, apathy, anosognosia

[a]Clinical Manifestations of Huntington Disease occur in three domains: motor (defining feature of the disease), cognitive, and psychiatric.

occur first. Three carefully designed observational studies including individuals at risk for HD and early symptomatic HD (PHAROS, PREDICT-HD, TRACK-HD) have facilitated in-depth characterization of individuals followed longitudinally including the period of phenoconversion. The course of HD can be divided into several periods. During the premanifest period (from birth to approximately 10-15 y prior to phenoconversion), individuals are clinically indistinguishable from controls (presymptomatic phase). The prodromal phase, which follows, is characterized by subtle motor, cognitive, and psychiatric features leading up to phenoconversion. Phenoconversion is defined clinically, as unequivocally manifesting the extrapyramidal motor signs of HD, when HD is diagnosed.

Motor Signs

The extrapyramidal movement disorder is the defining feature of HD and is characterized by both involuntary movements (chorea, dystonia) and impairment in voluntary movements (eye movements, gait, swallowing). The Unified Huntington's Disease Rating Scale includes a 124-point assessment of the motor signs of HD including eye movements (reduced saccades and breakdown of smooth pursuit), fine motor coordination, chorea, dystonia, and gait and balance (▶ Video 85.1). Chorea, derived from the Greek word "dance," is an involuntary movement that is brief but not as lightening-like as myoclonus. These random movements may be present in the limbs, face, or trunk (see ▶ Video 85.1). They are exacerbated with stress and are thought to disappear during sleep. Chorea tends to be present in the early symptomatic phase, peak middisease, and decline or disappear in the late phase of the disease. In contrast, bradykinesia, dystonia, and rigidity increase, particularly during the late stages of the disease, and affect voluntary movements. Most individuals need some assistance with walking, for example, assistive devices, approximately 7 years from onset of motor signs. Falls and choking are frequent mid-to-late stage events that may be life-threatening. In addition to chorea, other motor features include motor impersistence. Examples of motor impersistence include the inability to maintain tongue protrusion for 10 seconds or to maintain voluntary contraction while gripping, colloquially known as *milkmaid grip*. Impairments in fine motor activity that may include slowing and irregularity can be measured clinically or with quantitative motor assessment including speed of finger tapping and paced tapping. Variability of the inter tap interval or the pace of walking are among the earliest detectable signs of motor impairment, at a time when impairment is not detectable on neurologic examination or recognized by the individual. The earlier the disease onset, the less likely there will be chorea.

Children with juvenile HD present with an akinetic rigid form of the disease. Stiffness in the legs may also be accompanied by scissoring of gait, bradykinesia, and clumsiness. Chorea is uncommon among those who develop HD less than 10 years of age but may be seen in adolescents. Seizures occur in 25% of juvenile HD cases.

Cognitive Impairment

Although HD is diagnosed based on the presence of an extrapyramidal motor disorder, numerous cross-sectional and longitudinal studies have documented impairment primarily in executive function and psychomotor slowing that may begin 10 to 15 years prior to motor onset during the prodromal phase. Deficits in executive function including the ability to plan, organize, and monitor behavior are particularly prominent. These cognitive domains have been closely associated with the frontal lobes and the frontostriatal circuits and are similar to the cognitive impairment seen in Parkinson disease or vascular dementia. Patients with HD do not have a primary disorder of memory retention but have difficulty acquiring information efficiently or consistently retrieving it. In contrast to patients with Alzheimer disease, patients with HD show marked improvement in response to cued recall, similar to that in other patients with frontal lobe disease. Unlike the cortical dementias, such as Alzheimer disease, HD does not prominently involve language until late in the illness. Among individuals who are in the premanifest stage, deficits in motor planning/speed (eg, paced tapping, two-choice reaction time) and sensory-perceptual processing (emotional recognition and University of Pennsylvania smell identification test) best predict time to diagnosis after motor symptoms and CAG repeat length and age. Using traditional neuropsychological tests, 40% of premanifest individuals meet criteria for mild cognitive impairment (MCI) (using cutoff scores 1.5 standard deviation below the mean of a comparison group in at least one domain) and displayed mild impairments in episodic memory, processing speed, executive functioning, and/or visuospatial perception. The prevalence of MCI increases over the 10 years prior to diagnosis, as individuals get closer to their estimated age at onset of diagnosis. The majority have nonamnestic MCI (18%), followed by amnestic MCI (7.5%) in premanifest HD. During the premanifest period, individuals may recognize subtle functional decline in capacity to perform their jobs and handle financial affairs. Children present a special case. They often have cognitive decline, manifesting as poor school performance, characterized by poor attention and may be misdiagnosed as attention deficit disorder.

Behavioral Signs

A range of psychiatric manifestations can be seen in both premanifest and manifest HD including most commonly irritability, obsessive-compulsive symptoms (OCS), depression (in up to 50%), and apathy. Apathy may increase significantly in premanifest HD and is associated with prediction of functional decline.

Like apathy, OCS are referable to frontostriatal circuits, in particular the orbitofrontal cortex. OCS also increase over time as the individual approaches phenoconversion. Perseverative behavior that is not ego dystonic, for example, getting stuck on an idea, may also be seen. Anosognosia is frequent in HD. Individuals with HD are less likely to report motor symptoms that are present on exam than Parkinson disease patients. Almost half of the participants in the PREDICT-HD study who phenoconverted did not report motor symptoms, reflective of unawareness. Using the Problem Behavior Assessment Scale, three clusters of symptoms identified in manifest HD were depression, apathy, and irritability. Among HD patients, there is no clear relationship between psychiatric symptoms and disease progression, except for apathy, which correlates with disease duration. This lack of a relationship may reflect the availability of effective treatment for affective symptoms and the episodic nature of these symptoms. Suicidal ideation and suicide are more common in HD compared to age-matched controls. Completed suicide has been reported to be 7- to 12-fold more common in HD than controls. Psychosis is rare. Critical periods for suicidal ideation have been identified close to the time of phenoconversion and early in the early symptomatic stage. In children, behavioral changes may include depression, aggression, impulsivity, and obsessions.

Measures of Disease Progression

Clinical Progression Composite Measures

Composite measures of age, CAG repeat length, Total Motor Score (TMS) derived from the Unified Huntington's Disease Rating Scale (UHDRS), and the Symbol Digit Modalities Test can be used to predict probability of phenoconversion. A composite motor (UHDRS motor score), cognitive (Symbol Digit Modalities Test) and Stroop Word Reading (SWR) tests, and global function (Total Functional Capacity) all derived from the Unified Huntington's Disease Rating scale have been shown to provide an improved measure of disease progression in 1,668 individuals with early HD followed for up to 36 months. This measure is also associated with measures of corticostriatal atrophy.

Structural and Molecular Imaging

Structural MRI measures of striatal atrophy may be the earliest changes referable to HD but are not sufficiently sensitive or specific as a diagnostic marker for an individual patient. In longitudinal studies, these structural and functional imaging markers correlate with calculated time to disease onset based on CAG repeat length and UHDRS motor score. Diffusion tensor imaging, functional MRI, and fluorodeoxyglucose positron emission tomography are used in research settings as potential surrogate markers, however, are not yet useful for diagnostic purposes. A variety of neurotransmitters have been implicated in HD. Positron emission tomography studies have consistently demonstrated dysfunction of the dopaminergic system, primarily postsynaptic terminals (primarily D_2, but also D_1). Other neurotransmitter systems studied in small numbers of symptomatic and premanifest individuals include the GABAergic, endocannabinoids, adenosine, and phosphodiesterase, especially phosphodiesterase 10a. There has been recent interest in measures of neuroinflammation targeting activated microglia (Fig. 85.4).

Fluid Biomarkers

The most notable advance in the HD biomarkers field has been the development of sensitive and ultrasensitive assays for mutant and total HTT and the ability to measure neurofilament light (NfL) in CSF and plasma. CSF mutant huntingtin (mHTT) concentration has been associated in cross-sectional studies with clinical severity after adjustment for age and CAG repeat length and was shown to decrease in the first phase 1 or 2 Huntingtin-lowering trial, thus demonstrating applicability as a pharmacodynamics marker. NfL, a marker of neuronal damage is increased almost fourfold in plasma of manifest HD compared to controls and shows a clear gradient from premanifest to manifest, correlating with age, CAG repeat length, and whole brain volume. CSF NfL correlates with all brain measurements, more strongly than plasma NfL, although the CSF and plasma measurements are highly correlated. In a head to head comparison, NfL in plasma and CSF was significantly better than CSF mHTT in discriminating between premanifest and manifest HD, and NfL also showed stronger prediction for clinical and imaging measures in a cross-sectional study of 80 participants (20 controls, 20 premanifest, 40 early moderate symptomatic), suggesting the possibility that plasma and CSF NfL might be better measures of progression/discrimination in mutation carriers than mHTT. These two biomarkers that are restricted to clinical trials are early sensitive biomarkers that may improve efficiency of clinical trials.

MANAGEMENT

Treatment of Movement Disorder

Antidopaminergic Agents for Chorea

About 90% of people with HD develop chorea. Symptomatic treatment is advised if the chorea is functionally or emotionally disabling. Tetrabenazine (TBZ) LEVEL 1[1] and deutetrabenazine LEVEL 1,[2] a deuterated form of TBZ, are the only U.S. Food and Drug Administration (FDA)-approved medications for the symptomatic treatment of chorea. In a double-blind placebo-controlled study including 54 HD randomized to TBZ up to 100 mg and 30 to placebo, chorea was reduced by 23.5% after 12 weeks (NCT00219804). TBZ reversibly inhibits the central vesicular monoamine transporter type 2 and depletes presynaptic dopamine more selectively than norepinephrine and serotonin. The highest binding density for TBZ is in the caudate, putamen, and nucleus accumbens, where HD pathology is the greatest. Starting dose of TBZ is 12.5 mg daily titrated to 3 times daily with a maximum dose of 100 mg. At 50 mg, the FDA requires that cytochrome P450 2D6 (CYP2D6) genotyping be done. Poor metabolizers of CYP2D6 should not exceed the 50-mg dose. Because it is metabolized by CYP2D6, drug interactions that might raise TBZ need to be considered. It is generally well tolerated, but dose-dependent side effects include worsening depression, fatigue, parkinsonism, and akathisia. Tardive dyskinesia is not described. It was approved by the FDA in 2008. Deutetrabenazine was approved in 2017 for the treatment of chorea after a 12-week double blind placebo controlled study of 90 patients (NCT01795859) LEVEL 1.[2] Deutetrabenazine LEVEL 1[2] has a longer half-life than TBZ allowing for less frequent dosing. There have been no head to head comparisons of TBZ and deutetrabenazine.

A 26-week dose phase 2 dose ranging study of pridopidine (NCT02006472) LEVEL 1,[3] a dopamine stabilizer via D_2 receptors, including 408 participants, did not improve the UHDRS total motor score when compared to placebo.

Neuroleptics and atypical neuroleptics that block postsynaptic D_2 receptors have been studied in smaller trials but may

FIGURE 85.4 Positron emission tomography scans. Abbreviation: HD, Huntington disease. (Courtesy of H. Diana Rosas MD.)

be limited by side effects especially tardive dyskinesia and worsening gait and swallowing. Haloperidol, fluphenazine, and pimozide are high-potency typical antipsychotics that can suppress chorea but do have dose-limiting side effects. Similarly, small trials of atypical neuroleptics such as olanzapine, risperidone, quetiapine, and ziprasidone have been performed with mixed results. Treatment with these typical and atypical antipsychotics rather than TBZ or deutetrabenazine is advised if both motor and behavioral symptomatology is being addressed simultaneously.

Antiglutamatergic Therapy for Chorea

Glutamate toxicity resulting in degeneration of medium spiny striatal neurons is the concept behind treatment with *N*-methyl-D-aspartate receptor antagonists such as amantadine or compounds that disrupt glutamate transmission such as riluzole (NCT00277602) LEVEL 1.[4] These have been shown to have none to minimal symptomatic or neuroprotective benefits in level 1 studies.

Treatment of Dystonia

There have been no class 1 studies for dystonia in the setting of HD. Botulinum toxin injections can be also used for focal dystonia associated with HD.

Treatment of Voluntary Motor Impairment (Gait and Swallowing)

There are no medical treatments for the voluntary motor impairments (gait, swallowing); however, physical, occupational, and swallowing therapy could provide benefit in terms of reduced fall risk and psychological well-being and increased caloric intake. There have been no randomized controlled trials of exercise in manifest or premanifest HD.

Treatment of Weight Loss

Weight loss is also common as HD progresses. Increased caloric intake is necessary to maintain body mass index even in

the presymptomatic state when there are no obvious movements to account for increased energy expenditure. In manifest HD, weight loss is correlated with rate of disease progression. Weight loss may not only be attributable to severity of the extrapyramidal movement disorder, decreased caloric intake due to dysphagia, or depression but may also be due to a hypermetabolic state associated with HD. Attention to increasing caloric intake to maintain weight, particularly as the disease progresses, is essential for well-being. Pureed foods and thickened liquids and frequent small meals may improve caloric intake. Feeding tube placement is an individual decision that should be discussed well before the need in the later stages of the disease.

Treatment of Cognitive Impairment

There are no approved treatments for cognitive impairment in HD. Small studies have been conducted with cholinesterase inhibitors including donepezil and rivastigmine with no significant improvement. A randomized controlled trial of citalopram (NCT00271596) LEVEL 2[5] in nondepressed HD patients showed no change in executive function after 20 weeks; however, there was improvement in mood suggesting an effect on subsyndromal depression. The largest study to date included 403 HD participants at 64 centers followed for 6 months, randomized to latrepirdine (20 mg) versus placebo (NCT00497159) LEVEL 2.[6] This agent, thought to be a mitochondrial stabilizer, did not show a difference in performance on Mini-Mental Status Examination or Clinician Interview–Based Impression of Change.

Treatment of Psychiatric Symptoms

The FDA-approved medications for depression, irritability, obsessive-compulsive behaviors, and general anxiety and aggression have been used to treat individuals with HD. Data are confined to case series and small open-label studies. There are no class I studies specifically for the treatment of psychiatric symptomatology. A recently completed phase 2 trial (NT02507284) of SRX246, vasopressin 1a receptor antagonist, was evaluated for safety and tolerability in two doses compared to placebo in HD patients with irritability.

Disease-Modifying Therapies

No disease-modifying therapies have been approved for HD. Disease-modifying therapies have been directed primarily at oxidative stress and mitochondrial mechanisms of action but more recently have focused on reducing inflammation and strategies to lower mHTT.

Improving Mitochondrial Function and Reducing Oxidative Stress

A 5-year phase 3 study including 609 HD participants randomized to CoQ10 2,400 mg or placebo and followed for 60 months was stopped early because of futility in 2014 (NCT00608881) LEVEL 2.[7] A 3-year phase 3 study of creatine 40 mg/d was also stopped early in 2014 for futility (NCT00712426) LEVEL 2.[8]

Immune Modulation

Laquinomod (NCT02215616) is a small molecule immunomodulator that raises levels of brain derived neurotrophic factor (BDNF) failed to improve the total motor score when compared to placebo. An ongoing study of the first monoclonal antibody for treatment of HD is testing safety and tolerability of antisemaphorin 4D in 240 individuals (NCT2481274).

mHTT Huntingtin-Lowering Strategies

There are currently three main strategies for reducing HTT messenger RNA (mRNA) through posttranscriptional inhibition: antisense oligonucleotides (ASO), RNA interference compounds and small molecule splicing molecules.

Reduction of expression of mHTT has focused on preventing posttranscriptional processes and promoting early degradation of mRNA with ASO, through the recruitment of RNasesH1, an endogenous enzyme that recognizes RNA/DNA duplexes and degrades HTT pre-mRNA. There are two types of ASOs that are in clinical development, one that is nonspecific lowering both the mutant and normal HTT and the other allele-specific targeting two specific SNPs within the mutation but not the wild-type allele, accounting for 75% of all HD patients. The first trial using the nonspecific HTT-lowering ASO (1b/2a) has been completed in 46 early HD patients over 3 months (NCT02519036) LEVEL 2.[9] The compound, administered intrathecally by lumbar puncture every 4 weeks, was well tolerated and resulted in a dose-dependent 40% lowering of CSF HTT concentration. An open-label study is now ongoing, and a phase 3 study has begun. The allele-specific phase I to II studies (NCT03225833/46) are ongoing. It is currently unknown what the long-term effects of lowering normal HTT are, so potentially an allele-specific strategy that targets only mutant HTT may be important.

Administration of small interfering RNA results in cleavage and degradation of mature, spliced *HTT* RNA in the cytosol. Because double-stranded RNA does not distribute well throughout brain tissue, it is necessary to deliver the small interfering RNA stereotactically to striatum or cortex via viral vector such as adeno-associated virus. Because the virally delivered RNA interference permanently transduce central nervous system cells (gene therapy), this is envisioned as a one-time therapy that will suppress mHTT. Several different enhanced delivery methods are under consideration, and both cortex and striatum are being considered as targets.

Other strategies that are not yet in human clinical trials include DNA targeting techniques such as zinc finger proteins and CRISPR/Cas9.

Small fetal transplant trials have been conducted, and one multicenter longitudinal study is ongoing. Results have been mixed, in part due to small sample size and patient selection criteria and differences in methodology (tissue type transplanted and numbers of cells transplanted).

Nonpharmacologic Treatments

There is preclinical evidence that exercise has the potential to modify disease progression from several mouse models. A systematic review of 20 studies found support for benefits of exercise and physical activity on motor function, gait speed, and balance LEVEL 2.[10,11] There has been no evaluation of long-term exercise interventions on participants' health and quality of life. The type of exercise (aerobic, strength training) has not been established, nor its effect on energy expenditure and potential weight loss. It may also be important to assess the effects of exercise in combination with pharmacologic disease-modifying interventions.

OUTCOME

The course of HD is generally 15 to 20 years from the time of diagnosis based on the presence of an extrapyramidal syndrome consistent with HD. The course of juvenile HD rarely exceeds 15 years. The most frequent cause of death is aspiration pneumonia, although accidents, especially subdural hematoma, are common. Increasing attention to the benefits of weight maintenance and balance training may be life prolonging. The completion of three well-designed observational studies of at risk and early symptomatic individuals (PHAROS, TRACK-HD, and PREDICT-HD) as well as a large multinational clinical platform ENROLL-HD for clinical and biologic data will facilitate the design of new clinical trials that are adequately powered to detect change at all stages of the illness.

Parkinson Disease 86

Peter LeWitt

KEY POINTS

1. Beyond classic motor impairments, Parkinson disease (PD) patients often develop nonmotor problems (autonomic, cognitive, psychiatric, or behavioral).
2. Although PD is generally a sporadic disorder, genetic mutations associated with Parkinsonism have highlighted a variety of disease mechanisms.
3. Symptomatic therapy for PD has several medication and surgical options, some of them recently introduced.

INTRODUCTION

Parkinson disease (PD) is the most common movement disorder associated with neurodegeneration. Most of its characteristic features were elegantly described in an 1817 monograph written by a British general practitioner, James Parkinson, MD. What he described is in part a motor disorder, variable in symptoms and disabilities but with core manifestations of slowed movement (bradykinesia), decreased dexterity, gait disorder, and, in some instances, increased muscle tone (rigidity) and limb tremors at rest. Some patients don't initially (or ever) experience the full range of signs and symptoms possible in this disorder, and the clinical course often varies greatly from patient to patient. Early on, the experience of developing PD can be insidious and subtle, remaining undiagnosed for months to years. Eventually, many patients find resonance with the engaging descriptions of the disorder reported by James Parkinson, such as ". . . the hand fails to answer with exactness to the dictates of the will."

Clinical Features constituting unequivocal diagnostic criteria are still a matter of opinion. As a practical matter, even experienced clinicians recognize that PD diagnosis is a probabilistic decision because clinical manifestations of PD overlap with those of other neurodegenerative disorders that also can develop in patients at a similar age. PD is just the most frequently encountered of disorders manifesting motor impairments of *parkinsonism* (also termed as *parkinsonian syndrome*). The clinical grounds for making the diagnosis of PD is somewhat based on exclusion of other options. For a firm diagnosis of PD to be established, some authorities have argued that at least two "cardinal" features are needed, with at least one of them resting tremor or bradykinesia.

Most clinical forms of Parkinsonism (Table 86.1) arise from neuronal loss or degeneration in a discrete pathway of the brain originating in the substantia nigra pars compacta (SNpc), which projects to the striatum. As one of the early pioneers of PD research, Oleh Hornykiewicz, termed it, ". . . parkinsonism can be envisioned as a striatal dopamine deficiency disorder." Conceptualizing the varieties of parkinsonism can be by division of them into categories representing etiology: primary neuronal degeneration, secondary (acquired) due to structural and similar lesions, or as parkinsonism with neuronal degeneration associated with additional clinical manifestations (the so-called Parkinson-plus syndromes). Parkinsonism can also be due to a specific neurotransmitter synthesis deficit, such as an inherited disorder that is specifically lacking in enzymatic synthesis of dopamine. This condition, which generally has a benign clinical course, is known as *dopa-responsive* or *diurnally fluctuating dystonia* and is discussed elsewhere in this book under discussion of dystonia syndromes.

For the most part, *primary parkinsonism* refers solely to PD, which has characteristic pathologic and neurochemical changes. PD is sometimes referred to as *idiopathic PD* because its cause (or causes) is unknown. Recent studies have emphasized the challenges even experienced clinicians face for making a definitive diagnosis. For example, using rigorous consensus diagnostic criteria (based on autopsy-proven cases [United Kingdom Parkinson's Disease Society Brain Bank criteria]), the Parkinson Progression Markers Initiative has enrolled more than 400 cases of early PD for biomarker studies. Of these enrollees, more than 1 in 7 initially did not show evidence for a deficit in dopaminergic neurotransmission on radioisotope neuroimaging of striatal dopamine transporter (DaT) concentration. Such cases have been described as *symptomatic without evidence of dopaminergic deficits* (SWEDDs). The pathologic basis for SWEDD has not been established, and the existence of a clinical syndrome indistinguishable from PD challenges prior assumptions that we have a complete understanding of what produces all the signs and symptoms of PD. In any case, the clinical disorder we know as parkinsonism—that is, with its characteristic clinical features along with unmistakable neuropathologic and neurochemical changes—can be either sporadic or familial. Its clinical phenotype hasn't changed in several decades over which it has undergone intensive study by the neurologic research community. PD is the second most common neurodegenerative disease after Alzheimer disease (AD). In addition to motor manifestations, PD has several nonmotor features whose importance have been increasingly being recognized as adding to the long-term disabilities of PD. These problems range from fatigue, impaired sleep, behavioral disturbances, autonomic dysfunction, and various sensory symptoms.

Despite the SWEDD paradox, the motor symptomatology of PD seems to be a consequence of decreased dopaminergic neurotransmission primarily in the putamen. This neurochemical pathology can be modeled in animals rendered parkinsonian by neurotoxins or by substantia nigra (SN) lesioning. For most of the parkinsonian disorders listed in Table 86.1, there is a shared finding of degeneration in the dopaminergic projections due to loss of SNpc neurons. In some of these disorders, the brain pathology is more extensive than in PD; among their degenerative changes is the additional loss of postsynaptic dopaminergic receptors within the striatum. The lack of therapeutic effect by

TABLE 86.1 Classification of Major Parkinsonian Syndromes

Extrapyramidal Syndromes
• Parkinson disease—sporadic and genetic (Mendelian and non-Mendelian inheritance)
Secondary (Acquired) Parkinsonism
• Drug induced by dopamine receptor antagonist or dopamine depletor
• Hemiatrophy—hemiparkinsonism-syndrome
• Hydrocephalus; normal pressure hydrocephalus
• Hypoxic encephalopathy
• Various viral infections causing encephalitis; encephalitis lethargica
• Metabolic; parathyroid dysfunction with cerebral calcium deposition
• Toxicity from manganese, carbon monoxide, cyanide, or 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine exposure
• Trauma in region of midbrain extending to basal ganglia
• Tumor in basal ganglia, midbrain, or interrupting nigrostriatal pathway
• Vascular; multi-infarct state
The Most Common Parkinson-Plus Syndromes
• Corticobasal degeneration
• Dementia syndromes
◦ Alzheimer disease (some cases)
◦ Dementia with Lewy bodies (some cases)
◦ Frontotemporal dementia (some cases)
◦ Lytico-Bodig (Guam parkinsonism-dementia-ALS)
◦ Motor neuron disease–parkinsonism
• Multiple system atrophy (MSA) syndromes and their abbreviations
◦ Parkinsonism: formerly known as *striatonigral degeneration* (MSA-P)
◦ Autonomic impairment: formerly known as *Shy-Drager syndrome* (MSA-A)
◦ Cerebellar impairment: formerly known as *sporadic olivopontocerebellar degeneration* (MSA-C)
• Progressive pallidal atrophy
• Progressive supranuclear palsy
Heredodegenerative Diseases
• Neurodegeneration with brain iron accumulation
• Huntington disease (Westphal variant)
• Lubag (X-linked dystonia-parkinsonism)
• Mitochondrial cytopathies with striatal necrosis
• Neuroacanthocytosis
• Wilson disease
Parkinsonism With Neurotransmitter Enzyme Deficit
• Enzymatic deficiencies of dopamine synthesis

Abbreviation: ALS, amyotrophic lateral sclerosis.

dopaminergic therapy in these disorders is probably explained by the degenerative changes beyond the limited loss of presynaptic dopaminergic innervation characteristic of PD. In man, the motor symptomatology of parkinsonism can be created by reversible pharmacologic interventions with drugs (reserpine and tetrabenazine) that deplete presynaptic dopamine or inhibit its neurotransmission by blocking postsynaptic receptors (such as most antipsychotic drugs, prochlorperazine, and metoclopramide). The basis for how certain structural conditions leads to parkinsonism (such as hydrocephalus or striatal deposition of calcium) is uncertain. Studies of striatal electrophysiology have provided a picture of the deranged signaling in parkinsonism, in which decreased dopaminergic activity results in altered "downstream" neuronal firing in circuits passing to the subthalamic nucleus (STN) and the globus pallidus interna (GPi).

During the 1960s, emerging knowledge about the biochemical pathology of the brain culminated in dopamine replacement therapy. Subsequently, understanding about physiologic changes in poststriatal brain pathways led to surgical interventions for improving tremor, dyskinesia, and other problems of PD with ablation and, later, with electrical stimulation of GPi, the STN, or ventrointermediate nucleus of the thalamus. Today, the latter approaches have become the most prevalent treatment approaches beyond medications for PD. Modulating downstream circuitry beyond the striatum through localized electrical stimulation (termed *deep brain stimulation* [DBS]) has the potential to go beyond the best that medications can offer for managing PD.

As mentioned above, the symptomatology and disabilities of PD are more than dysfunctional striatal and poststriatal circuitry and the corresponding motor impairments. Sleep disturbance, orthostatic hypotension, anxiety, depression, cognitive decline, drooling, constipation, and other nonmotor problems are commonly reported by patients as adding to difficulties of living with PD. For most of these problems, their origin and treatment are unrelated to impaired striatal dopaminergic neurotransmission. Underlying these disturbances are the more extensive involvement of neuronal degeneration (particularly in the brainstem), and other neurotransmission changes found throughout in the PD brain and systemically.

EPIDEMIOLOGY

The predominant cause of parkinsonism is PD (see Table 86.1), a disorder whose incidence and prevalence increases with age. In the general population, the prevalence of PD is estimated to be 1% to 2% in the older than 60-year general population. The median age for onset of motor symptoms has been reported from many research groups to hover between 55 and 60 years, although an estimated 5% of cases begin younger than 45 years. When age of onset is younger than 20 years, the term *juvenile Parkinsonism* has been used. In the general, the development of parkinsonism earlier than the fifth decade increases the likelihood that disorder might differ from typical PD pathology, possibly due to one of the genetically associated forms of parkinsonism (Table 86.2) or to another neurodegenerative disorder. Several heredodegenerative diseases, including Huntington disease, Wilson disease, and pantothenate kinase 2-associated degeneration, rarely present as juvenile parkinsonism. By convention, the onset of parkinsonism between 20 and 40 years is defined as *young-onset PD*. In this group, there is also increased likelihood for a hereditary disorder.

TABLE 86.2 The Major Genetic Forms of Parkinsonism

Name and Locus	Gene	Mode of Inheritance	Pathologic and Clinical Features	Protein Function	Where Found
PARK1 and 4 4q22.1	*SCNA*	Autosomal dominant	Lewy bodies; earlier onset and more aggressive course; L-dopa–responsive parkinsonism, dementia, hallucinations, autonomic dysfunction	*α-Synuclein* possibly synaptic vesicle trafficking, elevated in bird song learning	Families in Germany, Italy, United States (Contursi kindred), Greece, Spain
PARK8 12q12	*LRRK2*	Autosomal dominant	Pathologic pleomorphism; indistinguishable from idiopathic PD	Dardarin, a GTPase and kinase, has diverse functions in signalling pathways and cellular functions	Worldwide
PARK2 5q26	*PRKN*	Autosomal recessive	Often juvenile onset without Lewy bodies; slowly progressive; no dementia	Parkin, a ubiquitin E3 ligase, attaches short ubiquitin peptide chains to a range of proteins, likely to mark degradation; supports mitophagy	Ubiquitous, originally in Japan, very common in juvenile onset
PARK6 1p36.12	*PINK-1*	Autosomal recessive	Juvenile onset	Mitochondrial kinase, modulates mitochondrial dynamics; supports mitophagy	Families in Italy, Spain, Philippines, Taiwan, Israel, Japan, Ireland, and North America
PARK7 1p36.23	*DJ-1*	Autosomal recessive	Early onset	Possible atypical peroxiredoxin and may play a role in apoptosis	Families in Holland, Italy, Uruguay
Glucocerebrosidase 1q22	*GBA*	Autosomal dominant; susceptibility gene; low penetrance; most common genetic risk factor gene	Indistinguishable from idiopathic PD	Lysosomal enzyme	About 13% of sporadic PD in Ashkenazi Jews; found in all ethnic groups

Abbreviation: GTPase, guanosine triphosphate hydrolase; PD, Parkinson disease.

PD arises more commonly in men, with a male-to-female ratio of approximately 3:2. Estimates of PD prevalence in modern populations vary widely but seems to be between 100 and 200 per 100,000. Annual incidence has been estimated as about 20 per 100,000. Because both prevalence and incidence increase exponentially with age, the prevalence is approximately 550 per 100,000 in individuals at age 70 years, whose incidence is approximately 120 per 100,000 annually. In addition to clinically diagnosed parkinsonism, autopsy studies show that the pathologic substrate of PD can be found in individuals not manifesting parkinsonism during life, indicating that studies of incidence and prevalence of occult PD underestimate the disease.

PATHOBIOLOGY

Pathology

The pathology of PD is distinctive and is easily distinguished from other parkinsonian disorders. Degeneration of the neuromelanin-containing neurons in the upper and lower brainstem is prominent. In the midbrain, involvement is selective for the loss of dopamine-synthesizing neurons in the ventral tier of the SNpc and in the norepinephrine-synthesizing neurons of the locus ceruleus. In addition to marked attrition of neurons, many of the remaining neurons in these nuclei contain characteristic cytoplasmic proteinaceous inclusions known as *Lewy bodies*, a pathologic hallmark of PD. Dopaminergic neurons from the SNpc project to the putamen and, to a lesser extent, to caudate nuclei (the neostriatum). Clinicopathologic correlations have shown that, by the time that parkinsonian symptoms arise, at least 60% of dopaminergic neurons in the SNpc already have been lost, and the striatal dopamine content is also greatly reduced. Brains of persons without clinical features of PD can have incidental findings of Lewy bodies at neuropathologic examination, perhaps representing the earliest stages of this disorder.

The Lewy body has become the topic of great interest in PD research because this intraneuronal eosinophilic inclusion is largely composed of ubiquitin and aggregated α-synuclein (αSyn). αSyn is a synaptic protein normally present in the brain and throughout the body. In addition to Lewy bodies (Fig. 86.1), clumps of αSyn positive can be found intra-axonally in involved neurons; these are termed *Lewy neurites* (Fig. 86.2). Lewy bodies and neurites are not exclusive to PD; these inclusions are also the hallmark of neurodegeneration within nondopaminergic cortical neurons of patients with one form of progressive dementia, whether or not they are also present in SNpc or locus coeruleus. Next to AD, cognitive decline associated with Lewy bodies (cortical Lewy body disease) is the most common form of progressive dementia. Other neurodegenerative disorders are recognized to have aggregated and misfolded αSyn, (although without the characteristic appearance of Lewy bodies with their intraneuronal rounded inclusions with a hyaline core). These alternative disorders, termed *synucleinopathies*, include multiple system atrophy (MSA), in which αSyn inclusions are exclusively within oligodendrocytes. Misfolded αSyn deposition can be found also in neurodegeneration with brain iron accumulation, which also exhibits cerebral neuronal pathology composed of axonal spheroids containing αSyn.

Neuropathologic studies of brains from elderly individuals either with or without PD have revealed an ontologic pattern for

FIGURE 86.1 Six stages of Parkinson disease (PD) based on distribution of Lewy neurites in the brain. Staining for α-synuclein in Lewy neurites reveals their distribution. The *darkest color* represents the most intense deposition of Lewy neurites and their earliest appearance, which is in the olfactory tubercle and dorsal motor nucleus of the vagus. The substantia nigra develops Lewy neurites at stage 3, following which symptoms of PD appear (Braak stage 4). The neocortex is involved in stages 5 and 6. The susceptible neurons belong to the class of projection neurons with an axon that is disproportionately long, thin, and poorly myelinated or unmyelinated. (From Braak H, Bohl JR, Müller CM, et al. Stanley Fahn lecture 2005: the staging procedure for the inclusion body pathology associated with sporadic Parkinson's disease reconsidered. *Mov Disord*. 2006;21[12]:2042-2051.)

development of αSyn pathology. In these studies, αSyn antibody staining for Lewy bodies and Lewy neurites indicates that this protein aggregates first in the anterior olfactory nucleus and in nuclei of the caudal brainstem, especially in the dorsal motor nucleus of the vagus in the medulla (see **Fig. 86.1**). Such findings arise without pathologic involvement of SNpc, from which PD's motor features emerge. After an extensive study of aging brains from persons without clinical manifestations of PD, Braak and colleagues proposed a staging system for the αSyn pathology of PD based on the timing, location, and relative abundance of Lewy bodies. From these observations, he proposed a hypothesis that the Lewy body–related pathology follows a characteristic pattern of progressive rostral spread from brainstem to the telencephalon and cerebral cortex (see **Fig. 86.1**). Braak's research suggested a pattern of initial vulnerability possessed by certain neuronal groups as well as neuron-to-neuron transmission of the disease process. Although an appealing hypothesis, Lewy body pathology does not fully correlate with loss of neurons or their function, and many cases seem to differ from this hypothetical pattern of progression. Recent research has highlighted the evolution of Lewy body pathology from an origin in the gut or the olfactory bulb instead of lower brainstem. Considerable evidence supports the notion that misfolded αSyn behaves in a templating manner throughout a neuronal adjacent neuronal population like prion disorders.

The observations of Braak and colleagues have provided insights that have stimulated research seeking origins of PD throughout the body. Recent work supports the notion that aggregated αSyn could be generated initially in autonomic plexus of the colon. Some evidence has been presented that these aggregates could migrate (possibly retrograde via the vagus nerve) to the dorsal motor vagus nucleus in the medulla, where early Lewy body formation is often found. Aggregated αSyn can also be found in skin, salivary glands, and other sites throughout the body. One characteristic of cells susceptible for harboring Lewy neurites is their identity as a class of projection neurons with a thin axon that is disproportionately long as well as either partially or totally lacking in myelination.

Etiology

The cause or causes of PD remain unknown. Although more than two dozen genes have been associated with this disorder (a few determinant genes clearly linked to causing the disease, others known to enhance risk for developing parkinsonism), most patients with PD lack identified hereditary factors. Genome-wide association studies have probed increasingly larger populations in the search of additional mutation or other genetic factors, leading to new loci reported from time to time. One question raised from the frequency of incidental Lewy body disease is whether nongenetic mechanisms are a necessary part of some of the genetically linked disorders. On this basis, research into PD causation has searched for environmental or lifestyle factors contributing to worldwide occurrence of PD. Undoubtedly, aging provides a strong component of the "backbone" for PD risk. However, it is unclear if increased occurrence of PD in the sixth decade and beyond necessarily reflects enhanced vulnerability at that period of life or, alternatively, just the result of cumulative lifelong events that haven't reach a threshold of disease expression at younger ages. Even advanced aging does not hold the answer—most centurions lack PD changes in their brains. Apart from the rare families whose parkinsonism reveals strong patterns of Mendelian inheritance (see below), PD in the general population is not found in clusters associated with work exposures, geographic location, exercise profile, diet, or other lifestyle factors. One of few exceptions to the latter is cigarette smoking, which, in dozens of epidemiologic investigations, has had a strong inverse-and dose-related association with reduced risk for acquiring PD. The reason for this lifestyle influence is unknown. A clinical trial using transdermal nicotine administration didn't demonstrate disease modification, but there is no other explanation of why chronic smoking confers an apparent protective effect. Although it has less of an apparent protective effect than smoking, caffeine intake is another life-experience factor shown to diminish risk for PD. Another unexplained inverse relationship with both occurrence and progression rate of PD has been concentration in serum and cerebrospinal fluid of the purine compound urate (a natural antioxidant which shares a chemical similarity with caffeine). The chronic use of lipid-lowering statin drugs, certain calcium channel blockers, and glucagon-like peptide 1 agonists have also provided evidence for lowering of risk.

Searches for causes of PD among the contemporary diet and modern lifestyle exposures to hundreds of synthetic chemicals need to consider that the same clinical disorder was well described by 19th-century physicians. Causation by a neurotoxic substance capable of the selective regional neuronal losses found in the PD brain seems unlikely. Years ago, an industrial chemical, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) was found to cause parkinsonism in exposed persons. This discovery raised the possibility that a similar compound in the environment might be responsible for PD. Rodents and nonhuman primates rendered parkinsonian by MPTP exposure have been useful laboratory models for testing symptomatic PD therapies.

FIGURE 86.2 Effect of different dosages of levodopa on the severity of Parkinson disease based on changes in the Unified Parkinson Disease Rating Scale (UPDRS). Data are from the ELLDOPA study in which subjects with early, untreated Parkinson disease were randomized equally to one of three doses of levodopa (with carbidopa) or placebo. Treatment lasted 40 weeks, after which the medication was tapered to zero over 3 days, and the subjects were evaluated 7 and 14 days later. The changes in subjects treated with levodopa at different dosages or with placebo were determined based on the total score of UPDRS. The scores were obtained by the blinded treating investigator who performed the evaluations before the morning dose of the daily dose of the study drug. The points on the curves represent mean changes from baseline in the total scores at each visit. Improvement in parkinsonism is represented by lower scores and worsening by higher scores. Negative scores on the curves indicate improvement from baseline. The bars indicate standard error. The last 2 weeks (weeks 40-42) allowed a return of symptoms and signs, but those on levodopa did not reach the same degree of worsening seen in those treated with placebo. (Data from Fahn S, Oakes D, Shoulson I, et al; and Parkinson Study Group. Levodopa and the progression of Parkinson's disease. *N Engl J Med.* 2004;351[24]:2498-2508.)

Although this compound imparts highly selective damage acutely to the dopaminergic neurons in the SNpc as in PD, MPTP exposure doesn't recapitulate the range of brain changes such as development of Lewy bodies. Other chemical exposures have been under suspicion for causing PD. For example, epidemiologic investigation of agricultural workers found an increase in PD risk associated with exposure to chemicals used in that industry. However, searching for the cause(s) of PD needs to consider that it lacks regional clustering or enhanced prevalence among occupations or lifestyle habits. As further confirmation of its ubiquity in the human population, PD is found in societies not engaged in the modern Western world's lifestyles.

In the absence of an identified cause for sporadic PD, research needs to contend with the possibility that it might arise from innocuous experiences in everyday life (such as viral upper respiratory infections) or factors derived from microorganisms in the colon (the microbiome). Genome-wide searches have regularly expanded the connection between PD and various genes and epigenetic factors. Another insight to the nature of PD was a 20th century disorder that was termed *encephalitis lethargica*, or von Economo disease. This seemingly epidemic form of parkinsonism spread over a worldwide for over a decade starting in 1918. Although its cause was never determined, it was suspected to arise in the aftermath of the worldwide influenza pandemic. Despite its clinical similarities to PD (including levodopa responsiveness), the full clinical syndrome of encephalitis lethargica and its neuropathology is greatly different.

Genetics

Although careful concordance studies of identical twins didn't find strong evidence for a genetic side to PD, a revolutionary change arose from the 1997 report of Mendelian inheritance of parkinsonism. Observed in a few families in the Contursi region of Southern Italy, these findings provided insights not only into these rare instances of hereditary parkinsonism but also into sporadic PD. The Contursi parkinsonian's shared feature was a mutation in a gene coding for αSyn. As mentioned above, an aggregated form of αSyn is the signature constituent of Lewy bodies. The role of the mutation (A53T) in the αSyn gene (*SNCA*) drew attention to the universal role of this vulnerable protein, even in cases regarded as "sporadic disease." With discovery of the role played by A53T, the search began for other gene mutations that might enhance risk for acquiring parkinsonism. These findings also reinforced thinking that PD etiology might be multifactorial, combining genetics with environmental contributions. The reporting of familial parkinsonism has swelled the number of identified genes (see Table 86.2). The varied clinical phenotypes of genetic forms of parkinsonism, as well as their neuropathologic findings, have raised questions as to whether each of these forms of parkinsonism should necessarily be classified as PD. In any case, the most salient features of genetic parkinsonism have to do with age of onset and their brain pathology (specifically, whether Lewy bodies are present). Several gene mutations listed in Table 86.2 are associated with parkinsonism

beginning before 50 years of age. In general, younger onset PD has a higher likelihood of an underlying genetic association. In the latter disorders, additional neurologic deficits beyond typical changes of PD parkinsonism can be found. Brain tissue deposition of iron and the absence of Lewy body pathology in some of the genetic forms of parkinsonism add to the puzzle of how closely they are related to sporadic PD.

As mentioned above, the first insight into genetic parkinsonism was discovery of mutations on *SNCA* (chromosome 4q22.1), which codes for αSyn. Also termed *PARK1*, this autosomal dominant genotype results in parkinsonism closely resembling sporadic PD, although age of onset is typically younger. Occasional instances of novel single nucleotide polymorphisms in the *SNCA* gene have been found in cases without a family history of parkinsonism. Although the mutant form of αSyn inevitably forms the aggregates found in Lewy bodies, another identified genetic aberration offers insight into why sporadic PD is associated with the protein in its normal ("wild-type") form. In another familial parkinsonian disorder classified as PARK4 (see **Table 86.2**), the mechanism is just the overproduction of native (wild-type) αSyn. In this instance, parkinsonism results from dysregulated gene activity (either from duplication or triplication of gene translation). These findings suggest the intrinsic vulnerability of αSyn as a precursor for forming Lewy bodies based on rate of synthesis or its intraneuronal concentration. Researchers are uncertain whether the Lewy body imparts toxicity to the neurons that harbor them, or, alternatively, if their formation constitutes a protective mechanism to sequester misfolded αSyn before it spreads and overwhelms vital cell functions.

In addition to highlighting αSyn's role in neuronal degeneration, genetic research has unearthed other mechanisms pertinent to neuronal degeneration. PARK8 (see **Table 86.2**) is gene defect (in leucine-rich repeat serine/threonine-protein kinase 2 [*LRRK2*]) that contributes to familial risk for parkinsonism. This mutation usually leads to a gain of enzymatic function. LRRK2 is ubiquitously expressed throughout the central nervous system and serves multiple functions. The full story of LRRK2's relationship to the development of parkinsonism is uncertain. However, mutant LRRK2 protein has been associated with diminished degradation of αSyn and decreased autophagy. Many pathogenic *LRRK2* mutations have been identified. *LRRK2* mutations constitute the most frequent genetic cause of parkinsonism, accounting to up to 5% of familial cases arising in the European population. Certain ethnic groups have even higher prevalence. For example, the most common *LRRK2* mutation, G2019S, has an increased frequency among Ashkenazi Jewish heritage (18.3% of those with parkinsonism) and in North African Berbers (39%).

LRRK2 mutations result in an autosomal dominant form of parkinsonism that closely resembles sporadic PD. Genome-wide association studies have shown that *LRRK2* polymorphisms also can be found exist in populations of sporadic PD. Although the neuropathology associated with *LRRK2* mutations tends to be highly variable (some cases exhibit Lewy bodies, whereas others manifest only neurofibrillary tangle pathology), degeneration of dopaminergic neurons within the SNpc is a constant feature.

When familial parkinsonism develops younger than the age of 30 years, the most common gene defect has been found in the PARK2 locus (*PRKN*). This gene codes for an E2-dependent E3 ubiquitin–protein ligase, parkin. Parkin gene mutations result in a slowly progressive, autosomal recessive parkinsonism characterized by resting tremor and clinical improvement after sleep. In contrast to typical sporadic PD, PARK2 offers a more benign long-term clinical outcome. In this disorder, no Lewy bodies are found even though SNpc neurons undergo degeneration. To add to the complexity of the story, a few adult-onset cases of PARK2 have been found to possess a single heterozygotic gene mutation; in these cases, SNpc Lewy bodies have been found. Two additional recessively inherited forms of younger onset parkinsonism include those with PTEN-induced putative kinase 1 (*PINK1*; PARK6) and *DJ-1* (PARK7) mutations. These mutations lead to defective regulation of the mitophagy pathway. These disorders have been associated with impaired mitochondrial functions such as management of intracellular oxidative stress. For both disorders, their clinical characteristics include an autosomal dominant early-onset form of parkinsonism and slow clinical progression.

Another relatively common site for mutation-associated with parkinsonism is the gene for glucocerebrosidase (*GBA*), located on chromosome 1q21. In homozygous individuals, a mutation in *GBA* has consequences for lysosomal function that lead to Gaucher disease. Heterozygous carriers of *GBA* mutations have increased risk for developing parkinsonism. Their clinical presentation is mostly indistinguishable from the sporadic disorder, although it can begin at a younger age and its outcome is associated with increased incidence of cognitive decline. Epidemiologic research has shown that about 13% of PD patients with Ashkenazi Jewish heritage possess this mutation (which is also found, less frequently, in other populations).

Pathogenesis

Evidence from examination of the PD brain and from various animal models of this disorder has provided a wealth of information about this disorder, although many gaps remain in understanding its pathogenesis. Two major themes of disease origin and progression have been discussed above, one centering on misfolded αSyn and the other guided by mechanistic insights from genetic forms of parkinsonism. The emerging role of the colonic microbiome has added another dimension of an endogenous bioenvironment capable of modulating immune system function, inflammatory molecules, neurotransmitter synthesis, and αSyn aggregation (among other options). In the still-fragmentary view of PD pathogenesis, concepts of a common final pathway have emerged with a focus on proteinopathy, impaired mitochondrial function, and multiple sources of oxidative stress. Insights from neurotoxins that can cause experimental parkinsonism also have been influential in considerations of how PD arises. Some of these toxins selectively target mitochondria function and generate oxidative stress. Postmortem biochemical observations have shown that complex I activity of mitochondria is reduced in SNpc of patients with PD. Such a defect will result in decreased adenosine triphosphate synthesis and buildup of free electrons, leading to release of free radicals. The brain in PD (particularly, the SNpc) shows depletion of reduced glutathione, one of the major intracellular antioxidants for quenching reactive oxygen species. Similar changes have been found in brains manifesting incidental Lewy bodies. Reduced glutathione synthesis might be the one of the earliest biochemical abnormalities of PD. It is not known, however, if such changes could cause PD or might just be a consequence of chronic oxidative stress from other causes.

Iron deposited in the SNpc may contribute to oxidative stress because the ferrous ion catalyzes the formation of the highly

reactive hydroxyl radical from hydrogen peroxide, which is a product of mitochondrial metabolism. Recessive genes with mutations associated with parkinsonism (as discussed above) may have roles at contributing to a mitochondrial etiology of parkinsonism. For example, *PRKN* and *PINK1* mutations confer wide-ranging effects on mitochondrial quality control such as regulating mitochondria biogenesis, maintaining fission-fusion balance to remove damaged mitochondria, mitochondrial transport, and turnover of damaged mitochondria by recruiting autophagic machinery. Another recessive gene, *DJ-1* is implicated in a pathway that handles oxidative stress. Endogenous factors may also predispose melanin-containing monoaminergic neurons to neurodegeneration. Cellular oxidation reactions (such as enzymatic oxidation and autooxidation of dopamine and other monoamines) result in the formation of reactive oxygen species such as dopamine quinone and other metabolic products that can damage the monoamine neurons in SNpc and locus coeruleus. Dopaminergic and noradrenergic neurons (the latter found in locus coeruleus) are autonomous pacemakers and possess long, highly arborized axons. These features lead to high metabolic demands in their cell bodies. The presence of a vulnerable calcium channel may predispose these neurons to basal metabolic stress by excessive calcium entry (another mechanism possibly predisposing to cell death).

Most of the genes whose mutations are associated with parkinsonism interact with multiple cellular functions. Nonetheless, those genes linked to recessive forms of PD have been implicated more for altering mitochondrial and metabolic pathways, whereas genes associated with autosomal dominant forms of PD tend to be involved with protein degradation homeostasis. As mentioned above, new evidence points to toxicity of protofibrillar forms of αSyn. Intriguing experimental evidence suggests that abnormal forms of αSyn may exert a prion-like property of propagating its abnormal conformation, with spread along the neuronal projections and even across synaptic connections. Another consequence of aggregated αSyn is interference with neuronal vesicle recycling. LRRK2 plays a role in vesicular trafficking and cytoskeletal function. Another gene whose mutation is associated with parkinsonism, vacuolar protein sorting 35 (*VPS35*) has been associated with autosomal dominant and levodopa-responsive parkinsonism. *VPS35* encodes a subunit of the retromer complex involved in endosomes and vesicular recycling. Both αSyn and LRRK2 influence protein degradation pathways, including autophagy (a process of cell degradation against dysfunctional cellular components by lysosomes). As mentioned above in the section on genetic forms of parkinsonism, a gene mutation limiting synthesis of the lysosomal enzyme *GBA* has been recognized as one of the most common risk factors.

CLINICAL MANIFESTATIONS

Signs and Symptoms

PD's clinical manifestations impairments emerge insidiously from a prodromal phase. The only category of evidence currently available for recognizing a preclinical stage of PD is detection by neuroimaging of diminished dopamine synthesis. This can be inferred from diminished striatal dopamine turnover or reuptake ^{18}F-fluorodopa positron emission tomography (PET) or DaT scans. Imaging of αSyn, although a current goal of research, hasn't been achieved although promising breakthroughs in this goal have been reported.

Tremor

Often, the earliest manifestation of clinical PD is tremor (a repetitive to-and-fro flexion-extension or rotatory movement) that is experienced when a limb is at rest. When engaged in any motion, this tremor is abolished until that body part returns to inactivity and then, after short delay, re-emerges. Resting tremor can be limited to one finger but generally involves the entire hand. It tends to be a distal manifestation in limbs but can involve proximal muscles. The lips, tongue, and jaw can also exhibit a tremor of a similar frequency. The classic "pill-rolling" tremor of PD involves the thumb and forefinger (▶ Video 86.1). The resting hand tremor often increases during walking. Stress, concentration, or excitement leads to exacerbation. Some PD patients will have an action tremor and postural maintenance tremor.

The localization of resting tremor can remain unilateral. Some patients feel an internal sense of tremor not outwardly observed. Because such tremor can respond well to antiparkinsonian medication, its origins would seem to be the same as observed tremor. Resting tremor may be the sole feature of PD for long periods of time, although eventually, it is joined by additional manifestations. For most patients, the diagnosis of PD is based on the concurrence of multiple clinical signs.

Evaluation of tremor in PD is sometimes confounded by tremor found with posture maintenance or during action. The latter type of tremor is the hallmark of essential tremor (ET). Ordinarily, these two tremor disorders are easy to distinguish, because the tremor of PD typically is abolished during action, the opposite of ET. Both PD and ET can manifest tremor with arms held in a forward-extended position. Sometimes, all three forms of tremor are found in the same patient, who might be affected by both PD and ET.

Bradykinesia

Another core feature of PD is *bradykinesia*. Although its literal meaning is "slowed movement," the clinical expression of bradykinesia is a spectrum of motor impairments that impart much of the disability and discomfort PD patients experience. All movements of an affected limb can be substantially slowed; for example, a patient may require several seconds for arising from a chair. The pace of gait may be at a fraction of normal. One of the most reliable indicators of bradykinesia (and one that patients can use as a guide to effectiveness of their medication regimen) is repetitive tapping of the fingers or feet. In addition to a slowed rate of movement, tapping also exhibits sequentially decreased amplitude as performance continues, a phenomenon termed *decrementing*. The progressive slowing of movements sometimes has interruptions that are momentary or last for several seconds. Another correlate of bradykinesia is *paucity of movement* (sometimes described as an en bloc quality of movement). These impairments reflect a reduction in the seemingly automatic features of movement. For example, the walking PD patient lacks fluidity of movement and exhibits reduced arm swing, smaller step length, extra steps at turns, and an overall reduction in use of supplementary muscle groups. Walking can be slowed with a shortened stride length a tendency to shuffle, and lack of a heel strike. The subjective experience of bradykinesia is sometimes described as clumsiness or incoordination. Such complaints should be kept in mind during the clinical examination because other motor deficits can coexist with parkinsonism. A careful exam should evaluate whether pyramidal tract deficits, action tremor, dyssynergia, or aspects of cerebellar system dysfunction are also present.

Patients commonly convey their experience of bradykinesia to the clinician as a feeling of weakness. A sense of fatigue, another common complaint reported by some PD patients even with mild symptoms, is sometimes tied correlated to the features of bradykinesia. Perceived weakness might also be regarded by some patients as feeling excessively tired, although it can be experienced in the absence of sleepiness. Evidence for bradykinesia is detectable in subtle behavioral manifestations such as the way a patient shrugs the shoulders. The underlying motor disorder of bradykinesia can also be brought out in everyday tasks for which slowness is not the only problem. For example, the lack of facility in handwriting leads to the execution of letters and words that are reduced in size, imprecise, and tending to trail off. Decreased dexterity in daily tasks is observed in difficulties at buttoning or placing arms in sleeves. Even face expression often provides a clue for bradykinesia. PD patients often develop parted lips and facial "masking," characterized a reduction in the muscular movements of blinking and facial expression. On this basis, PD patients are often thought be staring or experiencing a depressed mood.

Rigidity

Another clinical feature sometimes encountered in PD is a characteristic increase of muscle tone in limbs or axial musculature. This finding is termed *rigidity*. There can be an irregular quality of intermittent resistance during passive range of motion around the wrist or elbow joints, a phenomenon termed *cogwheel rigidity*. The tremorous or ratchety quality of cogwheeling is not the same thing as resting tremor superimposed on increased limb tone, nor is muscle rigidity the basis for bradykinesia. Cogwheel rigidity, like tremor and bradykinesia, is often regarded as a cardinal feature of PD. In some diagnostic schemes, criteria for establishing a "probable" diagnosis of this disorder can require observation of at least two of these manifestations. However, cogwheel rigidity is found in only about half of PD patients. Something like cogwheeling can also be observed in some patients with ET; this is termed *Froment sign*. For testing the latter phenomenon, an examiner carries out passive range of motion in a limb, whereas the other limb is engaged in voluntary active movement.

Postural Instability

Forward-flexed posture is a characteristic feature of PD. Commonly, it is first noticed in one or both arms and subsequently involves neck, trunk, and the legs. When severe, patients may have their trunk and head bowed downward (*camptocormia*).

Chronic flexion postures in the limbs lead to ulnar deviation deformities of the hands, flexion at the metacarpophalangeal joints, and extension of the interphalangeal joints (leading to the so-called *striatal hand* position). Inversion of the feet may develop, and the big toes may be dorsiflexed (the so-called *striatal toe*), whereas other toes curl downward. In addition to a forward-flexed position, the trunk in PD can be laterally tilted, a condition termed *Pisa syndrome*.

Dystonia

A dystonic equinovarus posture of the foot can evolve, sometimes with painful muscle spasms. The latter problem often arises early in the morning after awakening. Although imbalance generally does not occur in the first few years after parkinsonism emerges, afterward, a patient may evolve a characteristic balance problem.

Loss of postural reflexes is a unique PD feature that can be associated with falling backward despite the tendency for forward flexion of posture. This selective directionality of imbalance constitutes a milestone of PD progression that, for some patients, signals the end of safe walking or even standing unassisted. *Retropulsion* (a tendency to fall backward) can occur when a patient arises from seating or when walking backward. This problem can lead to falls because patients are unable to generate adequate response to prevent toppling even though there may be capability for recovery from the same extent of perturbed balance when occurring in a forward or sideways direction. To test postural reflexes, an examiner should use the *pull test*. The pull test is performed from behind a patient by abruptly pulling backward on the shoulders—this action is undertaken only after explaining the maneuver to the patient (▶ Videos 86.2 and 86.3). Normally, recovery of balance is achieved in one or two steps. If postural reflexes are greatly impaired, the patient may need to be caught, or else multiple steps may be needed to brake retropulsion. With impaired postural reflexes, a patient can collapse into a chair when attempting to sit. *Festination of gait* is another indicator of lost postural reflexes. In attempting to avoid falling backward, a festinating patient accelerates in quick forward steps.

Speaking and Swallowing

Another motor feature of PD is a change in quality of speech. Voice can become softer (*hypophonia*), and a monotonous tone can be acquired, with a lack of inflection (*aprosody*). Sometimes, enunciation becomes indistinct (*dysarthria*), or all generation of speech trails off to a whisper. Analysis of impaired speech might reveal that syllables are inadequately separated, resulting in words that run together (*tachyphemia*). An extreme version of stammering with characteristic repetition of a word's initial syllable is termed *palilalia*.

Swallowing may become impaired with advancing disease; with it, choking and aspiration can become concerns. Drooling of saliva can occur in PD, especially those with diminished facial motility. Drooling results from diminished spontaneous swallowing, not the excessive production of saliva in PD. In general, PD patients can swallow properly on a volitional basis, although it may require constant reminders from other to swallow so that drooling is avoided. Similarly, forward-flexed posture and arm swing can be normalized if the patient intentionally makes the effort to overcome these typical parkinsonian features.

Freezing

Freezing of gait is another distinctive PD phenomenon. Freezing is a sudden and transient event lasting from a few seconds to several minutes. It should not be confused with an undermedicated state because fully medicated patients can experience it. The triggers causing freezing can vary from patient to patient. As illustrated in ▶ Video 86.3, gait freezing can come on suddenly, with the impression of feet seemingly "glued to the floor". Abruptly afterward, the feet become "unstuck" and gait resumes. The distinctive patterns of freezing occur at the start of walking (*start hesitation*), freezing while executing a turn, and when approaching a destination. Freezing can be induced by walking through a crowded space. Passing through a doorway or walking in a crowd can trigger gait freezing. Patients may report that this problem might develop when hurrying while carrying out simultaneous tasks (such as holding an item in the hands), speaking, or during mental concentration. Curiously, freezing can be associated with "sensory tricks" that permit overcoming this problem by responding to visual clues (such as stepping over an imaginary object). The combination of freezing of gait and loss of postural reflexes together can lead to enhanced risk for falls. Besides gait, freezing can develop for other motor tasks. These include impaired eyelid opening (*apraxia*

of eyelid opening) or speech (the so-called *tip of the tongue* phenomenon), and pauses in handwriting.

Another curious feature of advanced stages of PD can occur when a patient is in an akinetic state. There can be the sudden reversal of immobility (termed *kinesia paradoxica*). As a phenomenologic mirror image of freezing, kinesia paradoxica refers the ability to quickly arise, walk, or use the limbs in response to a sudden and unexpected stimulus or emotional state. This phenomenon was first described in patients during the pre-levodopa era. The extremely brief reprise from immobility indicates that even with severe deficiency of dopaminergic neurotransmission in the PD brain, circuitry capable of enacting motor function is preserved.

Parkinson Mimics

At times of diagnosis and later during a parkinsonian disorder, clinical features may emerge that may point to a diagnosis other than PD. Often, it is the decline or lack of benefit from dopaminergic therapy. Additional problems may be clues such as incoordination, eye movement disturbance, autonomic impairment, or frequent falls. Because PD itself is not a uniform disorder in its signs and symptoms, it is important to highlight core diagnostic features while simultaneously excluding conditions mimicking PD. Surveys investigating large clinic populations of persons diagnosed with parkinsonism find progressive supranuclear palsy (PSP) to be the most common neurodegenerative disorder initially thought to be PD. Another less common disorder, MSA, can present with features of cerebellar system dysfunction or autonomic impairment.

Because both management and prognosis of PSP and MSA differ greatly from that of typical PD, early recognition is important (because it may be in the future if each of the parkinsonian disorders achieves specific disease-modifying therapy for these different neurodegenerative pathologies). Both PSP and MSA have distinctive brain magnetic resonance imaging (MRI) findings not found even in advanced PD. These are the *hummingbird sign* in a midline sagittal MRI view, which in the PSP brain is associated with midbrain atrophy. In MSA, atrophy in the cerebellum can be obvious on MRI, and a distinctive finding in the pontine tegmentum, termed the *hot cross bun sign*, is a characteristic finding. The development of severe imbalance and unexplained falling within 2 years of onset is typical of PSP but not PD. Symptomatic orthostatic hypotension and other autonomic impairment developing early in the course of parkinsonism is often the warning sign of MSA.

Clinical Course

PD is generally thought of as a progressive disorder. This description is accurate for most cases, although with the use of effective symptomatic therapy, any further progression of the underlying disorder remains hidden. The PD patient receiving effective treatment may exhibit a plateau in further clinical change for many years thereafter. The earliest months of clinical expression, when the first inklings of PD are observed, may provide the strongest evidence for disease progression. Initially, symptoms may be experienced only intermittently or during stressful situations, such as following a surgical operation or when pain is experienced. In about two-thirds of PD patients, resting tremor (often unilateral and intermittent) is the first recognized symptom (Table 86.3). Other single-sided presentations of PD, such as micrographia, are common and can persist for years. Eventually, most patients have bilateral symptoms and signs, although asymmetry can persist. The pace of progression in PD signs and symptoms has been followed prospectively in several clinical trials using the Unified Parkinson Disease Rating Scale (UPDRS), which catalogs parkinsonian features. Worsening in motor and functional disability generally result in roughly linear UPDRS score increases over several years of follow-up (see Fig. 86.2).

TABLE 86.3 Initial Symptoms in Parkinson Disease

Symptoms	No. of Cases (n = 183)	Percentage
Tremor	129	70.5
Stiffness or slowness of movement	36	19.7
Loss of dexterity and/or handwriting disturbance	23	12.6
Gait disturbance	21	11.5
Muscle pain, cramps, aching	15	8.2
Depression, nervousness, or other psychiatric disturbance	8	4.4
Speech disturbance	7	3.8
General fatigue, muscle weakness	5	2.7
Drooling	3	1.6
Loss of arm swing	3	1.6
Facial masking	3	1.6
Dysphagia	1	0.5
Paresthesia	1	0.5
Average number of initial symptoms per patient		1.4

From Fahn S, Kang UJ. Parkinson disease. In: Louis ED, Mayer SA, Rowland LP, eds. *Merrit's Neurology*. 13th ed. Philadelphia: Lippincott Williams and Wilkins; 2016:704–721.

Not all patients with PD become wheelchair-bound or bedridden, although this is an eventual outcome for a small fraction despite medications now available. Most commonly, this disorder, whether progressive or not, remains responsive to symptomatic therapy with levodopa and other medications. In addition, the option of electrical stimulation of basal ganglia structures—DBS—has expanded the options for achieving symptomatic control. However, the development of retropulsive imbalance—a finding which is generally unresponsive to either medication or DBS—calls for the use of supportive devices (like rolling walking frames) in order to maintain safe ambulation. The use of a cane is not likely to offer sufficient protection against falls.

The Hoehn and Yahr clinical staging scale (Table 86.4) captures typical aspects of PD progression. This scale was devised in the 1960s and was based on unmedicated PD patients (some of whom had been symptomatic for many years). It charts the transition from unilateral to bilateral manifestations (from stage 1 to 2) and, subsequently, to the loss of postural reflexes (stage 3). With the advent of levodopa, disability constituting stages 4 and 5 (wheelchair bound and bed bound, respectively) is much less common. Other ways to describe the impact of PD on activities of daily living are the Schwab and England scale and a section of the UPDRS dealing with independent functioning. The UPDRS has been updated and validated into a version that encompasses more of the nonmotor features of PD; this revision is termed *The Movement Disorder Society–UPDRS*.

TABLE 86.4 The Modified Hoehn and Yahr Staging Scale for Parkinson Disease

Stage 0	No signs of disease
Stage 1	Unilateral disease
Stage 1.5	Unilateral plus midline/axial involvement
Stage 2	Bilateral disease, without impairment of balance
Stage 2.5	Mild bilateral disease, with an abnormal pull test but with recovery to avoid falling
Stage 3	Mild to moderate bilateral disease; some postural instability (would fall on the pull test if not caught); physically independent
Stage 4	Severe disability; still able to walk or stand unassisted, but a walking aid is advisable to prevent falling
Stage 5	Wheelchair-bound or bedridden unless aided

Non-Motor Manifestations

Not surprisingly, some of the nonmotor symptoms of PD can be more troublesome than its motor manifestations. They are often more difficult to treat, or impossible. Nonmotor features comprise a wide range of problems that can arise either early or late during PD. Among them are behavioral and personality changes, including indecisiveness, apathy, social withdrawal, increased dependency, and passivity. Various changes suggesting of cognitive impairment can develop, including reduced attention span, impaired working memory and executive function, and visuospatial impairment. These changes can evolve even in the absence of overt cognitive decline. Eventually, some patients will undergo global worsening in cognitive abilities and will meet diagnostic criteria for dementia.

In PD, the patterns of cognitive impairment can be distinctive experiences. For example, many patients complain of hindered multitasking in everyday activities or a sense of slowed (although accurate) recall. The impact of nondementia cognitive impairments can intrude on work and social relationships. In some instances, these subtle declines in the thinking process will lead a spouse or another family member to take over decision-making tasks. Because of altered speaking and writing capabilities that some PD patients experience, the net effect may be diminished communicativeness. An aversion to participating in fatigue-generating tasks like exercise and long walks is a characteristic of some PD patients, even those who are physically quite fit. The prevalence of depression is increased in patients with PD compared to their healthy peers of similar age. It is important to recognize that depression is just as likely to be medication-responsive in PD as it is for others. Anxiety is another common problem, sometimes exacerbated by the daily challenge of inconsistent medication benefits and frustrations imposed by delays and impaired capabilities at participating in everyday activities.

Global cognitive decline in PD, like AD, is not inevitable, although a population older than 70 years of age has an increasing risk of dementia from several causes (of which AD is the most common). When cognitive impairment develops in a PD patient, it might be attributable to a second most common cause of progressive dementia, the formation of Lewy bodies throughout the cerebral cortex. In cortical Lewy body disease, short-term memory impairment may be less prominent as an early feature than typically encountered in AD. In contrast, PD dementia is often initially characterized by slowed responses to questions and other evidence of delay in cognitive processing—a condition that has been termed *bradyphrenia*. Some of the subtle features of bradyphrenia include deficiencies in mental and personality flexibility of thinking and difficulty at rapid change in mental sets (as, for example might be evident in psychological tasks requiring categorization). In a cross-sectional analysis of a typical PD clinic population, as many as one-fifth eventually experience go on to develop cognitive decline in association with cortical Lewy body disease, occurring within 10 years after diagnosis. Some estimates indicate that PD with duration greater than 10 years has an even higher prevalence of dementia. Whether a PD patient with progressive cognitive decline has abundant Lewy bodies in cortical neurons or AD pathology is not readily distinguishable during life. One distinguishing clinical feature that provides a clue for Lewy body pathology is the early occurrence of hallucinosis (even without the intake of drugs known to cause hallucinations).

Another nonmotor manifestation of PD is the perception of various sensory symptoms such as deep aches, burning pain, and tingling. These problems can arise in the absence of deficits in primary sensation modalities. A clue to the relationship of such sensory symptoms with PD is that they typically occur on the body side where PD first evolves, and they can remit with levodopa therapy. Sometimes, PD presents with a dull, diffuse pain in the upper arm pain in association with decreased arm swing while walking; this can be mistakenly attributed to a "frozen" shoulder until levodopa responsiveness is demonstrated. Akathisia (a near-constant state of discomfort leading to voluntary movements) and the restless limb syndrome (RLS) can be encountered in some PD patients. In both syndromes, uncomfortable sensations remit when the patient moves. Distinguishing these conditions can be difficult; akathisia is usually experienced throughout the day, whereas RLS typically arises in the evening. RLS also is characterized by crawling sensations in the legs and may be associated with periodic limb movements during sleep.

Sleep problems are common in PD, sometimes described by patients as frequent awakenings or fragmented sleep. One aspect of disordered sleep is attributable to a change in normal sleep architecture toward enhanced periods of dream-stage sleep during which rapid eye movement (REM) sleep predominates. The consequence of excessive REM sleep is the occurrence of a distinctive behavior disorder characterized by acting out of dreams in talking during sleep and repeated limb movements. This behavioral disorder can be responsive to treatment with benzodiazepine drugs. PD patients who have missed getting adequate rest during the night may go on to experience excessive daytime drowsiness. This problem can be exacerbated by treatment during the day with drugs that can cause sedation (like dopaminergic agonists).

Various patterns of autonomic disturbance can be encountered in PD. Some patients exhibit clear evidence of this when they have asymmetrical manifestations of PD, in that their skin temperature is cooler on the side with more motor symptoms. One common feature of autonomic impairment in PD is constipation, which is a frequent complaint in PD patients even if they take appropriate measures to avoid it. In PD, bladder emptying can be compromised, penile erection may be difficult to achieve, and symptomatic orthostatic blood pressure drops

may be experienced. Orthostatic hypotension can be exacerbated by dopaminergic medications. If there is prominent autonomic dysfunction early during parkinsonism, consideration of the diagnosis of MSA is warranted because the development of dysautonomia can predominate over the motor impairments. However, PD patients without MSA can also exhibit autonomic deficits.

Other systemic features of PD can be seborrhea and seborrheic dermatitis. In up to one-third of PD patients, marked reduction (hyposmia) or complete loss in sense of smell can precede the development of motor impairments, sometimes by years.

Muscle stretch reflexes are not impaired in PD, although a spontaneous extensor plantar posturing of the great toes is a dystonic manifestation that sometimes occurs with equinovarus foot posturing. This manifestation (termed *striatal toe*) mimics a Babinski sign, and often, the other toes are held in a flexed position. These dystonic manifestations tend to develop on the more affected side of the body when PD develops unilaterally. An unsuppressed reflex of obligate blinking (known as the *glabellar reflex* or *Myerson sign*) is commonly found, together with decreased spontaneous blinking.

DIFFERENTIAL DIAGNOSIS

For clinicians, the diagnosis of PD is based on both the typical profile of motor impairments and the absence of clinical features that would point to another disorder (such as the cerebellar dysfunction or autonomic impairments of MSA). The insidious onset of PD typically is often asymmetric (see **Tables 86.1** and **86.5**). The presence of resting tremor and cogwheel rigidity, although not a feature of all cases, is strongly supportive of the diagnosis. Added to examination features is the information gained from medication trials. In strong support of the diagnosis of PD is the improvement of tremor by amantadine or an anticholinergic drug and relief of all PD symptoms by levodopa. Because tremor is so commonly the earliest motor feature of PD, ET is not uncommonly confused with PD (see Chapter 76). ET is characterized by both postural and kinetic tremor but not the rest tremor characteristic of PD. ET can coexist with PD, but there is no obvious etiologic connection.

In PD, the morphology of the brain is normal on computerized axial tomography and MRI unlike PSP and MSA (as mentioned above). In PD, testing for impaired dopaminergic neurotransmission can be achieved with a commercially available study, DaT single-photon emission computed tomography (SPECT) using ^{131}I-ioflupane. Similarly, PET brain scans with ^{18}F-fluorodopa also can provide images to demonstrate decreased dopaminergic nerve terminals in the striatum. In interpretation of the DaT scan, the earliest stages of PD involve dopaminergic terminal deficit in the caudal region of the putamen region. DaT SPECT can be used to distinguish the diagnosis of PD from ET because in the latter condition, results are normal. Another PET study with a different ligand, ^{18}F-fluorodeoxyglucose PET can be used to reveal a distinctive hypermetabolism pattern in the lentiform nuclei and a metabolic network pattern that correlates with disease progression. A different metabolic network pattern in some PD patients has been associated with progressive cognitive decline, such a pattern also arises in other parkinsonian syndromes.

Clues that suggest that a parkinsonian patient is affected by a pathology different from PD can be subtle initially. Factors in favor of the diagnosis of PD include a one-sided presentation. In contrast, patients with other parkinsonian disorders commonly show symmetrical bilateral involvement (although a notable exception is corticobasal syndrome). Parkinsonism resulting from a localized head lesion, such as a subdural hematoma, can also be quite asymmetrical. Resting tremor also is in support of PD except when it is found in the context of drug-induced parkinsonism. As useful as these generalizations may be, they are not the final word on diagnosis of PD because patients can lack unilateral onset or resting tremor. One of the most important diagnostic aids beyond a convincing clinical story is improvement from a trial with a 300 to 600 mg/d levodopa regimen. Although PSP and other parkinsonian disorders can also show responsiveness early on, higher doses are generally needed for detecting responsiveness, and often, the benefits from levodopa are limited. Resting tremor in PD, however, can be unresponsive to all available medications (and sometimes, this is the reason for enlisting DBS as a therapy). Chapter 87 provides clinical descriptions of other parkinsonian disorders.

A number of rare neurodegenerative conditions can present with parkinsonism, including pantothenate kinase–associated neurodegeneration (which often shows a distinctive MRI abnormality, the "eye-of-the-tiger" sign) and neuroacanthocytosis (which has laboratory evidence including elevated creatinine phosphokinase and abundant acanthocytes on red blood cell smear). Huntington disease, which generally is a hyperkinetic movement disorder, can rarely present with prominent parkinsonism. Similarly, Wilson disease can lack its typical presentations with tremor and dystonia and instead can closely mimic PD. Virtually, all cases of neurologic Wilson disease will have abnormalities on MRI brain scans, but laboratory testing of urinary copper excretion or serum ceruloplasmin concentration can sometimes yield ambiguous results.

OVERVIEW OF PARKINSON DISEASE TREATMENT

At present, PD treatment is entirely symptomatic, targeted at controlling both motor and nonmotor symptoms of PD. The range of treatment options are listed in **Table 86.6** LEVEL 3.[1,2] For most patients, therapeutic choices should follow standardized guidelines, although to some extent the choice of medications can be individualized. For example, most patients don't need drugs that specifically target tremor because levodopa provides global effectiveness for most signs and symptoms. However, anticholinergic drugs and amantadine are available for addition to levodopa for enhancing tremor control. Response to medications (particularly levodopa) is dependent on the drug quantity at each dosing, and timing of medications may need to be tailored to a patient's report of benefits and various side effects (such as involuntary movements).

Among the general principles guiding treatment of PD is recognition that there is no reason to hold back on starting medication "early" (that is, when only mild symptoms have emerged). Patients sometimes encounter a myth that levodopa and other PD medications have a limited duration of benefit; using this logic, the argument of this misinformation is that putting off the start of treatment might be in their best interest. Another myth is that first-line treatment should be an inhibitor of monoamine oxidase B (MAO-B). The marketing of dopaminergic agonists over the past 35 years has sometimes implied that these drugs should be chosen as initial therapy or included with levodopa

TABLE 86.5 Clues Indicate the Likely Type of Parkinsonism

Clinical	Alternative Diagnoses
Never responding to levodopa	Other than PD
Predominantly unilateral parkinsonism	PD; HP–HA syndrome; CBS
Symmetric onset	PD; most forms of parkinsonism
Presence of rest tremor	PD; secondary parkinsonism
Lack of rest tremor	PD; Parkinson-plus syndromes
History of encephalitis	Postencephalitic parkinsonism
History of toxin exposure	Parkinsonism caused by the toxin
Use of neuroleptics	Drug-induced parkinsonism
Shuffling gait much greater than upper limb bradykinesia	Normal pressure hydrocephalus; vascular parkinsonism
Severe unilateral rigidity	CBS
Cortical sensory signs	CBS
Unilateral cortical myoclonus	CBS
Unilateral apraxia	CBS
Alien limb syndrome	CBS
Early onset of dementia	Dementia with Lewy bodies; AD; frontotemporal dementia
Psychotic sensitivity to levodopa	Dementia with Lewy bodies; AD
Early loss of postural reflexes	Progressive supranuclear palsy
Early onset of falling	Progressive supranuclear palsy
Impaired downgaze and opticokinetic nystagmus	Progressive supranuclear palsy
MRI: caudate atrophy	HD; neuroacanthocytosis
MRI: decreased T2 signal in striatum	Multiple system atrophy
MRI: midbrain atrophy ("humming bird" sign)	Progressive supranuclear palsy
"Apraxia" of eyelid opening	Progressive supranuclear palsy
Deep nasolabial folds	Progressive supranuclear palsy
Furrowed forehead and eyebrows (quizzical look)	Progressive supranuclear palsy
Excessive hesitation between words when speaking	Progressive supranuclear palsy; CBS
Nuchal dystonia	Progressive supranuclear palsy
Abducted arms when walking	Progressive supranuclear palsy
Square wave jerks in eye movement	Progressive supranuclear palsy; multiple system atrophy; CBS
Gait freezing	Progressive supranuclear palsy
Symptomatic orthostatic hypotension	Multiple system atrophy
Urinary or fecal incontinence	Multiple system atrophy
Cerebellar dysarthria and dysmetria	Multiple system atrophy, SCA2, SCA3, SCA17
Laryngeal stridor (vocal cord paresis)	Multiple system atrophy
Lower motor neuron findings	Multiple system atrophy; neuroacanthocytosis
Upper motor neuron findings	Multiple system atrophy
Early orofacial dyskinesia with levodopa	Multiple system atrophy
Laboratory	
Fresh blood smear: acanthocytes (>20%)	Neuroacanthocytosis
Greatly elevated creatine kinase	Neuroacanthocytosis
MRI: many lacunes	Vascular parkinsonism
MRI: "eye of the tiger" in pallidum	Pantothenate kinase–associated neurodegeneration type 2 (PKAN-2)
MRI: enlarged ventricles	Normal pressure hydrocephalus
Abnormal autonomic function tests	Multiple system atrophy
Denervation on sphincter EMG	Multiple system atrophy

Abbreviations: AD, Alzheimer disease; CBS, cortical-basal syndrome; EMG, electromyography; HD, Huntington disease; HP–HA, hemiparkinsonism–hemiatrophy; MRI, magnetic resonance imaging; PD, Parkinson disease; SCA, spinocerebellar atrophy.

TABLE 86.6 Therapeutic Options for Managing Parkinson Disease

- Dopamine precursor: levodopa combined with carbidopa (or outside of the United States, benserazide); available as immediate-release and sustained-release formulations, inhaled levodopa micropowder, and as intestinal gel for infusion
- Dopaminergic agonist: pramipexole, ropinirole, rotigotine (transdermal), and apomorphine (subcutaneous injection and sublingual tablets)
- Catechol-O-methyltransferase inhibitor: entacapone, tolcapone, opicapone
- Glutamate (NMDA receptor) antagonist: amantadine
- Monoamine oxidase type B inhibitor: selegiline, rasagiline, safinamide
- Anticholinergics: trihexyphenidyl, benztropine, ethopropazine
- Adenosine A_{2A} receptor antagonist: istradefylline
- Muscle relaxants: cyclobenzaprine, benzodiazepines, baclofen
- Peripheral antidopaminergic for nausea: domperidone
- Antidepressants: amitriptyline and other tricyclics, serotonin reuptake inhibitors
- Antianxiety drugs: benzodiazepines, buspirone
- Treatment of hallucinations and psychosis: clozapine, quetiapine, pimavanserin
- Treatments for dementia: rivastigmine, donepezil, galantamine, and memantine
- REM sleep behavior disorder: clonazepam, melatonin
- Antisoporific (daytime drowsiness): modafinil, caffeine
- Treatment for restless limb syndrome: dopaminergic agonists, gabapentin, and opioid compounds
- Treatment for sialorrhea: glycopyrrolate, propantheline, atropine drops, botulinum toxin injection into salivary glands
- Treatment for postural hypotension: fludrocortisone, midodrine, droxidopa, indomethacin

Surgical Approaches

- Ablative surgery and focused ultrasound
  - Thalamotomy
  - Pallidotomy
- Deep brain stimulation
  - Thalamic (Vim) stimulation for tremor
  - Pallidal (GPi) stimulation for parkinsonism
  - Subthalamic nucleus stimulation for parkinsonism

Abbreviations: GPi, globus pallidus interna; NMDA, *N*-methyl-D-aspartate, REM, rapid eye movement; Vim, ventrcintermedius.

from the start. Although several studies have investigated this question, there is no compelling evidence that there will be an advantage for starting with this class of drugs. Patients experiencing only resting tremor can obtain highly satisfactory responses to the anticholinergic drugs benztropine and trihexyphenidyl, or to amantadine; these might be the drugs of choice for some patients if levodopa fails against tremor. The choice of optimal PD medication is often conducted on a trial-and-error basis, governed by the understanding that medications should be introduced gradually and downward titrated if side effects intervene. Patients should engage in a cost-benefit analysis when expensive medications are considered. For example, choosing a sustained-release carbidopa-levodopa formulation may impose a financial burden for a patient whose convenience from a longer duration of action may be offset by the much higher out-of-pocket expense than its immediate-release generic alternative.

Levodopa

Since recognition of its effectiveness in 1967, L-dihydroxyphenylalanine (also known as *levodopa*) has been the mainstay of PD therapeutics LEVEL 1.[1,2] This large neutral amino acid serves as a precursor for dopamine synthesis occurring at nerve terminals within the caudate and putamen. At this location, endogenous dopamine production is reduced more than 50% by the time motor features of PD have emerged. As a charged molecule, dopamine doesn't cross the blood-brain barrier, but the entrance of levodopa is readily facilitated by an amino acid transport system. The transfer is highly dependent on serum concentration of levodopa and is saturable. Experimental evidence has shown that a plasma concentration of approximately 0.9 μg/mL is the threshold needed for generating an antiparkinsonian effect from levodopa. For many patients, this is achieved from oral ingestion of a levodopa dose of 100 mg combined with a peripherally acting levodopa-decarboxylase inhibitor (either carbidopa or benserazide). The latter decarboxylase inhibitors are equipotent on a per-milligram basis, and there is no advantage of one over the other. Benserazide is not available in the United States. Throughout the day, at least 75 mg of a decarboxylase inhibitor needs to be coadministered with levodopa for sufficient enzyme inhibition so that enough of the dopamine precursor will reach the brain for reversing parkinsonian symptoms. Without a decarboxylase inhibitor, several grams of levodopa would be needed daily to achieve optimal antiparkinsonian effect. For some patients, each levodopa dose needs to consist of quantities larger than 100 mg per dose to achieve full relief of parkinsonism. Occasionally, larger daily intake of the decarboxylase inhibitor is beneficial (and in the United States, carbidopa is available by itself).

A typical regimen of immediate-release carbidopa-levodopa 25 to 100 mg (or benserazide-levodopa) is taken 3 times per day (typically at 4- to 5-h intervals). The rationale for this regimen is the approximately 2.5- to 3-hour plasma clearance half-life of immediate-release levodopa which, for some patients, correlates with duration of its clinical effect. Although plasma concentration of levodopa are not monitored in clinical practice, a prescriber can assume that most patients will achieve a therapeutic (suprathreshold) levodopa effect with an intake of no more than 200 mg. Sustained-release carbidopa-levodopa formulations are designed to emit their contents slowly. Available formulations each offer less uptake from the gut (reduced bioavailability) than the immediate-release product, for which levodopa uptake is close to 100%.

Levodopa plus a decarboxylase inhibitor can be taken without food. Some patients recognize a delay in onset of levodopa effect when this medication is ingested with a meal. Hence, a plan for dosing 30 minutes before or 1 hour afterward can minimize drug uptake competition from meals. Another factor that can interfere with full absorption of a levodopa dose is the simultaneous intake of protein or other sources of amino acids. The proximal small intestine is where most L-large neutral amino acids are absorbed, and its facilitated transport mechanism has saturable kinetics. Hypothetically, dietary amino acids could compete with levodopa uptake to the extent that antiparkinsonian

effect is reduced. Some patients notice diminished effect when levodopa is dosed during a meal and attribute this result to the meal's protein content. However, most patients don't experience such an interaction. Patients can easily test whether protein restriction of their morning and midday meals results in improving levodopa responses.

In general, the major factor governing variable medication action with levodopa is irregular drug release from the stomach. Patients need to be instructed that fluid intake with swallowed tablets is necessary for facilitating reliable uptake. Using levodopa in the form of a tablet that melts in the mouth does not enhance uptake because levodopa is absorbed only in the proximal small intestine. The fastest that orally administered immediate-release levodopa reaches a circulating therapeutic concentration is 15 to 20 minutes. Crushing the tablets before swallowing, placing them in a carbonated beverage, or ingesting a warmed beverage, although sometimes advocated, does not lead to improved uptake. A reminder of the irregularity many patients experience with levodopa, even when it is taken on a 3-hour schedule, is summarized by a recent report in which endoscopy revealed an intact carbidopa-levodopa tablet in the stomach 1.5 hours after it was swallowed.

Although a pharmaceutical, levodopa also is an intermediate in the synthetic pathway of dopamine throughout the body. Levodopa is created from phenylalanine, which is subsequently converted to tyrosine. Supplementation with these amino acids, however, is not effective at increase dopamine synthesis. Once it enters the brain, levodopa is rapidly converted to dopamine and temporarily stored in presynaptic nerve terminals before its release or metabolism. Studies in rabbit brain showed that the turnover of dopamine molecules after arrival of levodopa to the brain lasts 15 minutes or less. Hence, the regularity of levodopa delivery is the key factor in maintaining uniform clinical effect for patients experiencing variability in levodopa effects. However, there is somewhat of a mystery involved in its action—the persistence of antiparkinsonian action long after a dose has been cleared from the circulation and passed through the striatum (where there is no storage or sustained release of either levodopa or dopamine).

What permits an enduring effect lasting for several hours (and to a lesser extent, up to 1 or more days later) is an inadequately understood phenomenon termed the *long-duration response* (LDR). The LDR is the basis for the common observation that, when levodopa is first started as a therapy, patients virtually never experience fluctuations in medication effect, even when oral intake is at intervals of 8 hours or longer. Study of the LDR suggests that the improvements of parkinsonian features outlast any possible effects of dopaminergic neurotransmission, implying that the explanation must be a downstream mechanism. The LDR is not specific to levodopa therapy because it has been detected with the use of the dopaminergic agonist, apomorphine. The loss of the LDR—which is when patients begin to experience dose-by-dose effects of immediate-release levodopa—leads to the *short-duration response* (SDR). The SDR is a milestone of levodopa therapeutics that, after 2 of more years of continued therapy, affects up to one-half or more of PD patients. For patients with SDR, this transition makes constancy of levodopa delivery to the brain critical for maintaining control of parkinsonism. At this point of a PD patient's "career" with levodopa, overlapping doses of medication and the use of adjunctive drugs become necessary for managing dose-by-dose fluctuations.

Improving on pharmacokinetic limitations of oral levodopa intake has been the theme of pharmaceutical development for many years. The concept of achieving continuous dopaminergic stimulation by enteral infusion of a carbidopa-levodopa microsuspension (also known as *levodopa-carbidopa intestinal gel*), is one product available in the United States. Its levodopa concentration is 20 mg/mL. Levodopa-carbidopa intestinal gel requires the insertion of an infusion tube through the abdominal wall into the stomach and passed beyond the pylorus to the duodenum or jejunum. The rate of infusing the microsuspension is adjusted for optimizing control of motor fluctuations. Less invasive approaches to gain better levodopa constancy has been the goal of several sustained-release carbidopa (and benserazide)-levodopa products. However, the performance of several marketed forms has been less than satisfactory at abolishing motor fluctuations. Currently, under investigation is subcutaneous administration of a solubilized carbidopa-levodopa formulation in order to achieve continuous infusion. As mentioned above, the problem of delayed or minimal onset of levodopa effect can be a consequence of ingested levodopa remaining in the stomach. A novel way to achieve rapid and reliable onset of levodopa effect has been created for on-demand use by patients experiencing the wearing off of levodopa effect. This product uses levodopa as a micropowder, which is inhaled in a fixed dose for an onset of effect that can be as short as 10 minutes later.

Levodopa-Induced Dyskinesias

Involuntary movements (dyskinesias) are an enduring pharmacologic consequence of chronic levodopa therapy. Their phenomenology comprises features of chorea, ballism, and dystonia, sometimes combining these categories of movement disorders. Dyskinesias emerge for up to one-third of levodopa-treated patients after 3 or more years of treatment, although these involuntary movements can be absent even after 10 or more years of levodopa use. Dyskinesias range in severity and are sometimes mild enough to be unnoticed by the patient. More severe forms can be disabling and limiting as to how much levodopa can be used. The incidence and severity of dyskinesias often increase as a function of duration and dosage of levodopa therapy. Sometimes they emerge early on, especially in young-onset PD and in those patients with severe clinical features of parkinsonism. The phenomenology of dyskinesias can be categorized according to the timing of levodopa dosing:

- Peak-effect dyskinesias, occurring simultaneous with timing of maximal relief of parkinsonian symptoms (typically, 30 min to 2 h after a dose of immediate-release levodopa).
- Diphasic dyskinesias, which begin to occur within 20 minutes after immediate-release levodopa is ingested and are absent during the peak-effect period. Curiously, dyskinetic movements again reemerge later at the end of the dosing cycle. Sometimes, the diphasic dyskinesia pattern is experienced by the patient only at the end of the dose effect when its occurrence can blend into the emergence of tremor or dystonia during "off" state (see ▷ Video 86.4).
- "Off" dystonia, characterized by painful, sustained cramps and occurring during undermedicated states. Initially, "off" dystonia may occur just after awakening in the morning ("early-morning dystonia"). It can be experiencing as painful foot cramps that are typically relieved by the first dose of levodopa and may be prevented by overnight use of a dopaminergic agonist.

Dyskinesias often keep company with wearing off motor fluctuations. In some patients, the levodopa cycle may change rapidly from severe peak-effect dyskinesias to severe "off" states; this process has been termed *yo-yoing*. During a levodopa cycle, such patients may experience only a brief "on" state. This situation has been described conceptually as a "narrow therapeutic window," although pharmacologic proof for such a phenomenon is lacking. Patients with yo-yoing can have prolonged periods of good antiparkinsonian control without any occurrence of dyskinesia or dystonia; however, the variability in drug effect (which is governed largely by the peripheral pharmacokinetics of levodopa) can result in a chaotic and disabling pattern of involuntary movements and "off" states.

Pharmacologic management of dyskinesias can be challenging because the balance between optimal control of parkinsonism and the side effect may be difficult to achieve consistently. It often requires a complicated medication regimen, with varying levodopa doses and timing between oral intakes as short as 2 hours. Risk factors for levodopa-induced dyskinesias have not been well defined. Among recognized contributions to the development of dyskinesias are certain dopamine D_2 receptor polymorphisms and younger age of PD onset. Why all patients don't develop dyskinesias is somewhat of a mystery because virtually all nonhuman primates rendered parkinsonian with the neurotoxin MPTP will develop involuntary movements after relatively short period of continued levodopa administration. Experience with animal models of parkinsonism have highlighted a possible role for pulsatile dopaminergic stimulation as a key factor in the generation of dyskinesias (which, once initiated, persist). The prevention of levodopa-induced dyskinesias has been a challenge to researchers and clinicians alike. Avoiding any use of levodopa should be successful but this comes with the price of depriving patients from the most effective means for controlling parkinsonism. Using sustained-release preparations of levodopa has been proposed to lessen the risks, based on the notion that reduced pulsatile dopaminergic stimulation of the striatum might be beneficial. However, randomized controlled studies testing this hypothesis with comparison to immediate-release (and, hence, more pulsatile) levodopa formulations did not find that dyskinesias were avoided or were less frequent.

Limiting daily levodopa intake (by an arbitrarily defined maximal dose) does not appear to reduce risk for dyskinesias. Researching the question of dyskinesia avoidance can be problematic because a patient receiving a low-dose levodopa regimen and not manifesting dyskinesias might nonetheless have initiated the mechanism for involuntary movements, but these are never observed if the levodopa regimen is insufficient for unmasking the latent dyskinesias. Monotherapy with a dopaminergic agonist or coadministration with levodopa has also been posited as a means for avoiding the development of involuntary movements. However, a randomized controlled clinical trial showed that this strategy did not achieve its intended goal.

Levodopa and Adjunctive Therapies

Practical considerations in managing PD include the notion of tailoring therapy to a patient's needs and giving a thorough explanation for the treatment choices. Although polypharmacy might seem to be undesirable strategy (especially given the effectiveness of levodopa alone), combining levodopa with extension strategies (such as MAO-B and COMT inhibitors) can achieve a dosing schedule more convenient than the 2- to 3-hour intervals needed in patients experiencing the SDR and using immediate-release carbidopa-levodopa LEVEL 2.[1-5] Control of tremors may require adding an anticholinergic drug or amantadine to a levodopa regimen. The symptomatic benefit of a dopaminergic agonist combined with levodopa can be an extended relief of parkinsonian symptoms and improved control of dystonic symptoms. Maintaining independent functionality for as long as possible can require adjustment of medication to reflect new problems such as the onset of levodopa-induced dyskinesias, for which amantadine can be helpful as well as levodopa reduction to lower its peak concentrations.

Most patients do not need to use DBS to accomplish optimal control of parkinsonism. However, for those whose quality of life can be greatly improved by this procedure, it is important for clinicians to offer a balanced viewpoint on the benefits and of this intervention so that it can be realistically appraised. The physician treating PD should also be a strong advocate for regular exercise because there is compelling evidence of its impact on improved symptomatic control and quality of life LEVEL 1.[2,6,7] In some instances, referral to physical therapy may guide patients toward more independence and safer ambulation LEVEL 2.[8] A widely available physical therapy program targeted at the problems of PD goes by the name of Lee Silverman Voice Therapy (LSVT)–BIG. This program, developed by the same organization that also created PD-specific speech therapy, has further information available at www.lsvtglobal.com.

In the past, options for starting symptomatic treatment were regarded as a topic of controversy, the modern (and evidence-based) view is that there is no threat from starting medication even when symptoms are relatively mild. Even the earliest symptoms such as a mild tremor or facial impassiveness can have an impact on a patient's livelihood, social interactions, and other indicators for quality of life. Hence, it is important to recognize that a decision to withhold treatment may come with a price for the patient.

Concerns that levodopa might hasten dropout of dopaminergic neurons have been countered by the results of two randomized controlled trials, the 2004 ELLDOPA (see Fig. 86.2) and a delayed-start study of carbidopa-levodopa (published in 2019 by Verschuur and colleagues). Each of these studies provides evidence that levodopa treatment doesn't accelerate striatal neuronal loss. The ELLDOPA study provided a suggestion of a dose-related protective effect (see Fig. 86.2).

COMT Inhibitors

Efforts to improve consistent control of parkinsonism with levodopa can become increasingly challenging over time, even in patients for whom the underlying disease has not progressed. The waning of the LDR over the first 3 to 5 years after the start of levodopa therapy has inspired a search for other options to improve medication effectiveness. One way to extend the duration of levodopa effect is to block its metabolism to an inactive metabolite, 3-O-methyldopa, in the periphery. Much as the decarboxylase inhibitors block diversion of circulating levodopa to form dopamine, inhibitors of catecholamine-O-methyltransferase (COMT) can lessen the conversion of levodopa to 3-O-methyldopa. Three drugs in clinical use—entacapone, tolcapone, and opicapone—are reversible COMT inhibitors whose action extend the therapeutic plasma concentration of orally administered levodopa. The net result of adjunctive use of COMT inhibitors is approximately one-third extension of daily "on" time in patients experiencing wearing off with an immediate-release formulation of levodopa LEVEL 1.[5] The three COMT inhibitors differ in their dosing schedule; entacapone is given at 4-hour

intervals, whereas opicapone is administered once daily. Tolcapone is marketed as a 3-times-a-day medication. Unlike the others, tolcapone has been associated with extremely rare cases of hepatic failure, and so, monitoring of liver enzymes is recommended for prescribers. Although opicapone and entacapone are entirely peripheral in their COMT inhibitory actions, tolcapone has limited penetration across the blood-brain barrier and so might confer some of its antiparkinsonian action by retarding degradation of dopamine in the brain.

MAO-B Inhibitors

Another means for extending levodopa effect for the PD patient with motor fluctuations is through MAO inhibitors that are selective for the type B isoform (MAO-B). MAO-B provides one of the enzymatic pathways in the brain by which dopamine is degraded (the other pathway uses COMT). The three marketed MAO-B inhibitors—selegiline, rasagiline, and safinamide—act by retarding the catabolism of dopamine so that each neurotransmitter molecule remains for longer in the synapse. The net clinical result is like improvements gained from COMT inhibitors: approximately one-third more daily "on" time for patients experiencing wearing off between doses LEVEL 1.[1-5] MAO-B inhibitors used as a monotherapy also confer a small antiparkinsonian effect. They do so by amplifying dopaminergic neurotransmission in patients with relatively mild PD. Although clinically measurable, the clinical benefits of MAO-B inhibition are much less than levodopa would accomplish in the same patient. For this reason, there is little rationale for using MAO-B inhibitors as initial treatment. However, many clinicians do so, presumably with an unproven notion that "sparing" the use of levodopa achieves some useful purpose. Both selegiline and rasagiline have been studied in large-scale randomized controlled clinical trials testing a hypothesis that they might exert disease modification. The hypothetical mechanism of what MAO-B inhibition might achieve is diminished generation of free radicals produced by dopamine catabolism. Neither drug provided proof for achieving neuroprotection as a monotherapy in hundreds of newly diagnosed PD patients. However, there is a persisting perception of disease-modifying efficacy held by some clinicians, and so, MAO-B inhibitors continue to be prescribed as a first-line or an adjunctive treatment.

Amantadine

A serendipitous discovery in the late 1960s brought an antiviral drug, amantadine, into the PD armamentarium. For some patients, it has been the most effective treatment for tremor (even in patients for whom dopaminergic or anticholinergic drugs have failed). Subsequently, amantadine was found to be highly effective in some patients for suppression of levodopa-induced involuntary movements. This indication has recently become more established with the United States launch of a sustained-release amantadine formulation. Amantadine has also been found to extend the duration of action of levodopa in patients experiencing wearing off between doses LEVEL 1.[1-3]

The pharmacology of amantadine still has unanswered questions as to how it acts to achieve antiparkinsonian effects. For suppression of dyskinesias, evidence supports blockade at *N*-methyl-D-aspartate glutamate receptors. Amantadine also has anticholinergic properties, although this property is unlikely to explain its tremor suppression. Amantadine is particularly useful as an adjunct to dopaminergic therapy. It can also be used as a monotherapy for tremorous patients not needing additional antiparkinsonian effects.

Amantadine in its generic immediate-release form is typically dosed as 100 mg 2 to 4 times per day. The two sustained-release products in the United States are designed to deliver quantities like the immediate-release formulations. Amantadine is excreted largely unchanged, and so, its renal clearance needs consideration in patients with compromised kidney function is compromised. The drug's clinical benefits suggest that dosing at 4- to 6-hour intervals is optimal.

Adverse effects with amantadine include dryness of the mouth and eyes, and an increased tendency toward constipation. It can be sedating and can cause vivid dreaming and hallucinations. Some patients experience bilateral ankle swelling. A distinctive change in the appearance of the skin, livedo reticularis, develops in some patients treated with amantadine. This asymptomatic change in the skin is not an allergic reaction or reason to discontinue the drug except based on its cosmetic implications. Livedo reticularis (which can have other causes as well) is a prominent reddened and reticular mottling due to prominence of capillary fields. It especially evident in the skin surfaces distally in the legs and in the volar forearm skin.

Anticholinergic (Antimuscarinic) Drugs

Anticholinergic drugs were the first effective medications used for PD, preceding the levodopa era by several decades. However, they do not offer the range of benefits offered by levodopa, particularly for slowed movement and decreased dexterity. Anticholinergics act to lessen resting tremor and dystonic features of PD. The role of cholinergic neurotransmission in generating parkinsonian symptomatology is not well understood. For example, administration of centrally acting acetylcholinesterase inhibitors for cognitive impairment only rarely leads to exacerbation of motor impairments in PD. The effectiveness of anticholinergic drugs for resting tremor can be quite substantial, even in patients not showing response to dopaminergic therapy or amantadine.

Currently in the United States, only two anticholinergic drugs are marked for PD: trihexyphenidyl and benztropine. Another useful antitremor drug and available elsewhere is a phenothiazine-class drug, ethopropazine (used in a dose range of 25-50 mg 3 times a day). The central nervous system actions of anticholinergic drugs may be targeted at circuitry of striatal cholinergic interneurons, although the specific pharmacology of anticholinergics drugs hasn't undergone much investigation in the modern pharmacology era. Despite concerns about their tolerability and the limited range of parkinsonian symptoms that they can control, anticholinergic drugs are useful for augmenting dopaminergic therapy and amantadine.

With trihexyphenidyl 2-mg tablets, a common starting dose is one-half or one tablet, taken 3 times daily at 4- to 6-hour intervals. If showing efficacy, a few patients will benefit from and tolerate higher doses, increasing to as much as 15 mg/d. Benztropine has a greater per-milligram potency of antiparkinsonian effect (about 4 times greater than trihexyphenidyl) and so, typical dosing ranges from 0.5 to 2 mg 3 times a day. The doses of trihexyphenidyl and benztropine used in PD are the same as those that can be effective for treating both resting tremor and rigidity in parkinsonism induced by dopamine receptor blocking drugs. Anticholinergic drugs do not benefit all types of tremor such as ET and cerebellar outflow tremor.

Adverse effects from anticholinergic drugs are common, particularly in older patients. The central actions of the drug can interfere with short-term recall and other effects on cognition and the mind can include drowsiness, "fogginess" of thinking, and prominent hallucinations, or other psychotic manifestations (such as extreme suspiciousness). The peripheral side effects of anticholinergic drugs can be bothersome, especially when constipation, urinary retention (particularly in males), and dry mouth are experienced. Some guidelines advocate not using anticholinergics in elderly patients, but with cautious advance of a low starting dose, some patients with advanced age can both tolerate and benefit from the unique antitremor effect these drugs can confer. Other drugs with anticholinergic properties, such as amitriptyline, diphenhydramine, clozapine, and cyclobenzaprine, can also help in tremor suppression, and their sedative profile can make them useful choices for a PD patient bothered by tremor interfering with sleep.

For the frequently occurring peripheral side effects (often, the reason for discontinuing or limiting the dosage of anticholinergic drugs), there are some pharmacologic strategies to manage side effects: Pilocarpine eye drops can overcome dilated pupils leading to blurred vision. Pyridostigmine (up to 60 mg 3 times per day) can help to overcome dry mouth, urinary retention, and constipation.

Dopaminergic Agonists

Drugs that mimic the actions of dopamine had their first use in 1951, when a few patients briefly treated with apomorphine provided evidence that this drug could offer relief for parkinsonian symptoms. At the time, apomorphine dopaminergic properties were unknown, and discovery of dopamine's role in PD was still a few years away. The next phase of this story, reported in 1967, was the use of a dopaminergic compound related to apomorphine, N-propylaporphine, for relief of parkinsonism. Adverse effects limited further development of this drug. An orally administered semisynthetic ergot compound, bromocriptine, entered clinical practice for PD in 1974 as a potential alternative to levodopa. In addition, when used as an adjunctive therapy, bromocriptine offered improvement over maximal responses achievable with levodopa. The success of bromocriptine set off a search for other dopaminergic compounds that might provide improved potency, selectivity of effect, and better pharmacokinetic properties than levodopa.

Since 1974, more than two dozen dopaminergic agonists were developed and tested in clinical trials for antiparkinsonian effects. Due to similar effectiveness with most of these compounds, only a few went on to marketing. One of these, the ergoline pergolide, was withdrawn when it was determined that it conferred a risk for the development of heart valve fibrosis. Similar problems have been associated with the use of another ergoline, cabergoline. As risk for developing fibrosis affecting pleura, pericardium, and elsewhere was demonstrated for bromocriptine, fibrotic disorders appear to be an idiosyncratic outcome from chronic therapy with ergot-derived compounds. For this reason, compounds with different chemical structures now are the mainstay of dopaminergic agonist therapy, and fibrotic disorders haven't been reported with them.

Currently in the United States, pramipexole and ropinirole are available for treating PD as orally administered drugs. Another dopaminergic agonist, rotigotine, is administered by means of a transdermal patch. Each is for chronic use as monotherapy or combined with other PD medication. Although their pharmacologic properties differ somewhat, each is a potent dopaminergic agonist at D_2/D_3 dopamine receptor sites, which are abundant in the striatum. The per-milligram potency of pramipexole is approximately 4 to 5 times greater than that of ropinirole and rotigotine (which are approximately 1:1). Although these drugs can differ in their side effect profile, their overall antiparkinsonian effectiveness is similar. Overnight switch among them is possible because of cross-tolerance mechanisms for dopaminergic side effects. Although both ropinirole and pramipexole are marketed in sustained-release forms for once-daily administration, the immediate-release forms exert long durations of effect, as shown by several days required for washout of their clinical actions. While transdermal administration of rotigotine might seem to be a better way to achieve more continuous control of parkinsonism than the oral dopaminergic agonists, there isn't evidence in support.

The usual dosing schedule for both ropinirole and pramipexole is 3 times per day at intervals of 4 to 5 hours during the day. Rotigotine patches are applied once daily. The maximal daily dose of pramipexole is 6 mg/d (although patients rarely build up to that dose because of adverse effects or lack of further efficacy). Results from a dose-finding trial found that no further antiparkinsonian effect with daily intake greater than 1.5 mg. For ropinirole, the optimal dose range for ropinirole is much wider, and the drug can be prescribed up to 24 mg/d. One large-scale randomized clinical trial found that optimal daily dose averaged 15.5 mg/d. Rotigotine is typically used from 4-12 mg per day.

Apomorphine is available in the United States and elsewhere for intermittent subcutaneous administration when a patient determines that an "off" state needs reversal, often within 10 minutes. Doses of apomorphine for this purpose range from 2 to 6 mg, and injections can be used several times per day. Recently, a sublingual formulation of apomorphine has been approved in the U.S. Elsewhere in the world, apomorphine is also available for used as a subcutaneous infusion by a miniature pump in order to maintain continuous dopaminergic stimulation throughout the day and, in exceptional circumstances, throughout the night as well.

The place in therapy for dopaminergic agonists has evolved over the past three decades because clinical trials were conducted to learn if better outcomes could be achieved than with levodopa alone. Each of the marketed dopaminergic agonists can be used as monotherapy. Even with buildup to maximally tolerated doses, they lack the overall effectiveness of levodopa. For example, a long-term randomized clinical trial of ropinirole as monotherapy found that, starting in the second year, patients increasingly chose to augment this dopaminergic agonist with levodopa so that by the end of the study, only a small number successfully remained on ropinirole alone.

Dopaminergic agonists confer several adverse effects, including the risk of daytime sedation. Although drowsiness can be lessened by the slow buildup of dose, this side effect drowsiness is a dose-limiting effect for many patients. Other problems associated with each of the agonists can be lowering of blood pressure and ankle swelling. Dopaminergic agonists have a greater chance than levodopa for inducing hallucinations, particularly among elderly patients or those who have cognitive impairment. Vivid dreaming throughout the night can also accompany the start of a dopaminergic agonist.

Beyond the realm of adverse effects described above is another class of adverse effects for dopaminergic agonists that have been termed *impulse control disorders* (ICDs). Surveys have shown that up to 17% of patients treated with dopaminergic agonists at any dose can experience some form of ICDs (even those receiving these drugs for restless leg syndrome). ICDs are idiosyncratic

problems, without identified risk factors. Patients developing ICDs can take on one or more dysfunctional psychosocial behaviors, such as uncontrolled gambling, hypersexual acting out, binge eating, compulsive shopping, excessive hobby activities, and even unwarranted generosity. The consequences of an ICD can be devastating to the patient and family.

The risk for an ICD should be made known to patients and their families because this disorder can emerge at any time following the start of a dopaminergic agonist. Reduction in drug dose can sometimes help to improve the situation, but discontinuation may be the safest management strategy. Fortunately, ICDs usually are relatively rapidly reversible, and they do not persist when patients return to levodopa therapy alone. Abruptly, stopping a dopaminergic agonist poses the risk for a syndrome of withdrawal that can be avoided by slower reduction of this medication. The dopaminergic agonist withdrawal syndrome is a cluster of symptoms that can involve anxiety, irritability, other types of psychological distress, and various autonomic symptoms (nausea and vomiting, hypotension, flushing, and diaphoresis). There also can be a craving for return to use of the dopaminergic agonist in this syndrome, which can last for weeks to months.

Dopaminergic drugs can lead to other behavioral consequences. Punding (also known as *utilization behavior*) is a rare, idiosyncratic disorder with some resemblance to ICDs. This disorder, which has been described in amphetamine abusers, refers to intense repetitive handling and examining of objects, such as picking at oneself, taking apart devices, or continued sorting and arranging of commonplace objects. Punding behaviors have been reported in PD patients receiving levodopa or dopaminergic agonists. The only treatment is to discontinue the dopaminergic drug.

Adenosine A_{2A} Antagonists

A new class of drugs has joined the other nondopaminergic options for treating PD. Istradefylline, a highly selective antagonist of the adenosine A_{2A} receptor, has been recently approved for treatment of "off" episodes. Istradefylline is now marketed in the United States after several years of use in Japan. Studies with daily intake at 20 or 40 mg showed that levodopa-treated patients experiencing motor fluctuations had a reduction in daily "off" time. This clinical improvement was observed in patients who were receiving maximal treatment with dopaminergic therapies, including agonists and inhibitors of MAO-B and COMT. Istradefylline has a benign adverse action profile, the main side effect being a small increase in dyskinesias for some patients. The site of action for istradefylline is inhibition of adenosine type A_{2A} receptors that are selectively found in the indirect striatal outflow pathway.

TREATING THE NONMOTOR PROBLEMS OF PARKINSON DISEASE

Nonmotor features often arise concurrent with the development of tremor, slowed movements, and decreased dexterity. Some of these features, such as impaired sense of smell and REM sleep behavioral disorder, can precede the onset of motor features by several years and suggest earlier central nervous system involvement at sites beyond the nigrostriatal pathway. Collectively, nonmotor features may have the greatest impact on declining quality of life in PD 5 to 10 years after onset and beyond. Of course, the aging process is superimposed on the progression of PD, confounding the assessment of various changes in features such as ease of swallowing, balance, and voice dynamics. However, the challenge for the caring physician is to recognize and use available therapeutic interventions for treatable nonmotor problems.

Mental and Behavioral Complications

Although PD patients can develop cognitive decline due to progressive neuronal loss, the effects of medication can also be a cause (or can add to the problem). Like dopaminergic drugs, amantadine and anticholinergics can be the culprits. The range of problems can be sedation, confusion, agitation, vivid dreams, hallucinations, or paranoid thinking. The brain locations from which these problems arise are not known for dopaminergic drugs. Activation of dopamine receptors in nonstriatal regions (cortical and limbic structures) are likely sources, based on pharmacologic evidence of lowering dose or using dopamine receptor blocking drugs. Dose and potency of dopaminergic stimulation is a factor in this problem, as shown by the good tolerability of conventional levodopa doses in patients developing toxic mental side effects with even low doses of the much more potent dopaminergic agonists. On this basis, elderly PD patients are often suspected to be unable to tolerate the adjunctive use of dopaminergic agonists. However, published experience argues otherwise. In general, all PD patients (regardless of age or duration of disease) can develop dose-related psychosis from excessive intake of levodopa or dopaminergic agonists, amantadine, or anticholinergics. Because some patients experience delayed or incomplete emptying of orally administered medications from the stomach, sometimes an episode of confusion or hallucination can arise from an apparent overdosage of medication even when a patient is receiving a conventional regimen.

As in primary psychotic disorder like schizophrenia, hallucinations and other psychotic phenomena in PD patients can be lessened or completely blocked by medications targeting dopaminergic D_2 receptors in the brain. All members of the latter class of psychiatric drugs can be used for this purpose; however, they carry the risk of simultaneously diminishing striatal dopaminergic neurotransmission (and thereby worsening control of parkinsonism). Two antipsychotic drugs that can control hallucinations without exacerbating parkinsonism are clozapine and quetiapine (both dosed 12.5-50 mg/d and, occasionally, at larger doses) LEVEL 3.[8,9] The specific pharmacologic properties of these drugs making them useful in PD has not been defined, and they don't provide benefit for all patients. Clozapine is the more potent of the two, and it also uniquely has an antitremor action. The main drawback of clozapine is its rare risk of causing agranulocytosis. For this reason, regular blood testing (weekly for the first 6 months and at less frequent intervals thereafter) is mandatory for safe use of clozapine. Another option for treating psychotic symptoms in PD patients is pimavanserin. This drug does not block dopamine receptors but, instead, is a selective inverse agonist and antagonist selectively of serotonin 5-HT_{2A} receptors; it also has a low affinity interaction with 5-HT_{2C} receptors. Used at a standard once-daily dose of 34 mg/d, pimavanserin has been safe and effective at controlling hallucinations without exacerbating motor features of parkinsonism. There haven't been head-on comparisons between pimavanserin and the other antipsychotic treatment options. However, most clinical experience suggests that the effectiveness of pimavanserin differs from the others and may be complementary.

When a patient experiences develop the new onset of hallucination, agitation, or a confusional state, clinicians should keep in mind the possibility that other exacerbating factors may be

the cause. These include a low-grade infection (urinary tract or respiratory), dehydration, and adverse effects of other medications (such as urinary tract antispasmodics with anticholinergic properties). The onset of a progressive dementia can also cause episodic cognitive and behavioral symptoms. Supportive measures against "sundowning" (such as lights or soft music left on in the bedroom at night) can help. Lowering doses of medication and reassessing the continuing need for any adjunctive drugs besides levodopa can also help in the management of hallucinations and agitation. The reduction of dopaminergic agonists should be done gradually to avoid the possibility of causing the dopaminergic agonist withdrawal syndrome.

In the realm of disabling nonmotor features, none has as profound an impact as cognitive decline. Apart from the common problem of AD in persons of the same age range, impaired cognition can be encountered in PD patients due to intraneuronal aggregated αSyn. Like the β-amyloid burdened cortical and subcortical neurons in the AD brain, the pathology of cognitive decline in PD patients is extensive formation of Lewy bodies in brain regions linked to cognitive processes. Lewy body disease affecting cortical and subcortical structures comprises the second most common pathology associated with progressive cognitive decline. Lewy body pathology can coexist with AD. The consequences of neuronal dropout can add to the problems of increased sensitivity to medications used to treat PD. The clinician has a few clues that can point specifically to diffuse Lewy body disease pathology as the source of cognitive and behavioral disturbances. Early in the process (and sometimes unassociated with medications capable of causing hallucinations), hallucinatory phenomena, paranoid thinking, and failure of executive task completion (adequate decision making) may be evident. Although similar problems can occur in AD, their incidence seems to be increased in Lewy body disease.

If dementia develops in a PD patient, the goals of maintaining independent functionality can be challenging. Making the distinction between Lewy body and AD pathology isn't necessary for therapeutic decisions. A trial of an acetylcholinesterase inhibitor is generally the first choice LEVEL 2.[8-10] Drugs in this class include rivastigmine (1.5-6 mg/d), donepezil 5 to 10 mg/d, and galantamine (4-24 mg/d). Another drug that has shown effectiveness for symptomatic improvement of impaired cognition is memantine (5-20 mg/d). The combination of memantine with an acetylcholinesterase inhibitor may provide further benefit. Usually, clinical improvements are evident within a month of initiating these drugs (which offer only symptomatic benefits, not arrest in disease progression).

Developing depression is at increased risk for the PD patient. The same antidepressant medications effective in the general population can be used (except for nonselective MAO inhibitors). Selective serotonin uptake inhibitors are often chosen for this problem. However, a randomized, controlled clinical studies investigating treatment of depression in PD compared paroxetine with nortriptyline; the latter drug proved to be more efficacious.

Alprazolam, diazepam, and other benzodiazepines are usually well tolerated for treating anxiety. They can also help to lessen tremor by reducing reactions to stress that exacerbate tremor. The clinician should be alert to the occasional paradoxical excitation and agitation that benzodiazepines can cause, particularly in the elderly with dementia. Fragmented sleep, a common complaint of PD patients, can lead to daytime drowsiness. The clinician should attempt to differentiate PD-related causes for sleep disruption from those that can affect the general population (such as obstructive sleep apnea, restless leg syndrome, and nocturia). Many PD patients report frequent occurrence of vivid dreaming. Often, this is associated with changes in sleep architecture that can be identified on polysomnography (or from reports of the patient or bed partner) as REM sleep behavior disorder. There are only a few treatment options and include evening dosing with melatonin (4-6 mg) and clonazepam (0.5-1 mg). Unfortunately, not all patients respond adequately. REM sleep behavior disorder should be distinguished from nighttime hallucinations because the treatment options differ.

Hallucinations can seem to be a continuum from vivid dreaming. Sometimes, nightmare content is reported. For this condition, drugs with antipsychotic properties such as quetiapine, clozapine, and pimavanserin can be used (see descriptions and dosing considerations above). For excessive daytime drowsiness, the treatment options include morning dosing with sustained-release caffeine tablets or modafinil (100-200 mg). Reducing intake of daytime medications causing drowsiness (especially dopaminergic agonists and amantadine) can also be helpful.

Other Non-Motor Symptoms

Other nonmotor features associated with PD can develop with more advanced stages of the disorder. Orthostatic hypotension leading to postural faintness can be related to dopaminergic drugs; if so, changing the dosing regimen can help. Other measures include ensuring adequate daily intake of water and salt (the latter can be achieved by encouraging daily intake of a high-sodium food such as bouillon). Elevating the bedframe at the head of the bed can lessen overnight diuresis and blood pressure drop upon arising in the morning. Specific treatments for postural blood pressure drop include midodrine (5-10 mg 3 times a day) and droxidopa (100-200 mg 3 times a day). For the latter drug, limiting the daily intake of carbidopa may be necessary for obtaining maximal benefit. Avoidance of supine hypertension is a necessary component of treating postural hypotension.

Sialorrhea can be both an annoyance in PD. It is attributable due to a decreased rate of spontaneous swallowing (not excessive saliva secretion). A peripherally acting anticholinergic drug such as glycopyrrolate can be effective both when ingested orally or swished around the mouth in a small volume of water. If this option is ineffective, bilateral injection of botulinum toxin into salivary glands is often beneficial, lasting 3 months or more.

SURGICAL THERAPY

In PD therapeutics, functional neurosurgery is defined as the targeted use of lesioning or electrical stimulation to achieve improvements in tremors, dyskinesias, "off" times, and overall parkinsonian symptomatology LEVEL 3.[6,7] In general, functional neurosurgery is used for achieving goals that can't be achieved through medications (although PD drugs are generally continued). Stereotaxic lesioning of a region of the thalamus for tremor control—the ventrointermedius (Vim) nucleus—preceded the development of levodopa. Subsequently, with better understanding of basal ganglia motor circuitry, an ablative lesion in the GPi was determined to be a site for improvements in features of PD beyond tremor. For the past two decades, functional neurosurgery has shifted from lesioning to localized electrical stimulation with a methodology termed *DBS*. The "deep" in DBS refers to the

insertion of stimulating electrodes several centimeters from the skull into the target nuclei of the brain, which include the thalamic Vim, the GPi, and the STN. DBS has become an important way for treating PD if medication management has become suboptimal. After widespread international experience in more than 250,000 patients and several technologic advances, DBS has become an established option, although with limitations for what it can accomplish LEVEL 2.[6,7] DBS has capitalized on the discovery in the PD brain of functional roles conferred by "downstream" striatal outflow pathways. By use of high-frequency (60-150 Hz) DBS with 1 to 4 volt pulses, DBS therapeutics has had a major impact on quality of life in advanced PD. The procedure has also gained approval for use earlier during PD, with the notion that later problems of dyskinesias and motor fluctuations might be averted. However, most experienced clinicians use DBS today primarily for the treating problems of resting tremor and levodopa-induced dyskinesias or dystonia. Commonly, these problems can be completely abolished. DBS directed to the GPi is especially likely to provide control of dyskinesias or dystonia LEVEL 2.[6,7] Experienced clinicians at DBS sites generally develop a good idea of whether to use the GPi or STN for controlling other problems of PD, although stimulation at both sites can produce similar results. Although GPi and STN can also result in reduction of tremor for some patients, the best results will come from electrode placement in the Vim thalamus. However, this target poses risk for dysphagia or speech disturbance when carried out bilaterally; hence, a unilateral DBS procedure is sometimes chosen. The choice of DBS for advanced PD needs to keep in mind its limits; certain problems like retropulsive imbalance do not respond. Because electrode placement passes through frontal cerebral cortex, patients chosen for DBS should not have significant cognitive impairment. DBS electrode placement has been quite safe extensive clinical experience. However, it does pose the rare risks for intracerebral hemorrhage during the procedure or localized infection postoperatively.

A recent addition to therapeutic options for PD tremor is unilateral thalamic lesioning by means of focused ultrasound (FUS). Like the older surgical procedure of stereotaxic surgical lesioning of the thalamic Vim nucleus, FUS produces a localized thermolesion. FUS is carried out with an awake patient whose head is surrounded by multiple ultrasound transducers. The methodology of FUS involves ultrasound beams focused to intersect at a precise location within the skull, guided by real-time MRI imaging. Although a U.S. Food and Drug Administration–approved procedure, FUS is currently available at only a few treatment centers in the United States and internationally. Besides FUS, another surgery-free approach uses γ radiation to produce a localized lesion in the thalamic Vim nucleus for tremor control. This technique, termed *Gamma Knife*, has been available for many years. Like FUS, beams of γ rays are positioned around the skull to intersect around the desired thalamic target and using exposure parameters that have been generated by past experience in radiation-induced lesioning. The localized neuronal damage produced by a Gamma Knife procedure generally requires 6 months or longer to evolve and, like other methods of thalamic lesioning, is limited to unilateral use. Although excellent results have been accomplished at experienced centers, the procedure is not always successful at abolishing tremor, and some patients have developed radiation-induced necrosis with neurologic consequences beyond the targeted zone intended for selective lesioning. Most experienced clinicians would not regard Gamma Knife treatment as a first-line treatment for control of parkinsonian tremor.

OUTCOME

PD is often described as a "progressive' disorder, and, indeed, many patients will experience increasing symptomatology and disability over time. However, most PD patients are greatly improved by the various available treatment options and live normal lifespans. In the premedication era, the diagnosis of PD was followed by an expectation of premature death and inevitable loss of independent functioning. Although these stereotypes of PD continue from an earlier era, the PD patient today has very good chances of achieving control of PD motor symptoms.

One component of the image of PD as a progressive, disabling disorder is the subset of parkinsonian patients who turn out to have another diagnosis. The rapidly progressing patient initially might be recognized eventually as suffering from PSP or MSA. These disorders are sometimes recognized only after a period of medication unresponsiveness and the development of additional neurologic deficits. A PD patient affected with imbalance has the special challenge for avoiding falls that pose a risk for orthopedic and head injuries; these problems figure into the most common explanation for why a PD patient might have increased morbidity and occasional fatal outcomes.

Clinicians counseling patients with PD as to their future should always seek the "bright side" of PD. Most patients do well even on a long-term basis. The challenge for promoting this well-justified optimism is by becoming familiar with studies that have followed long-term outcomes of this disorder. Patients with PD should consider themselves as healthy and have a good chance to have a normal life ahead. For most PD patients, medication responsiveness can be counted on for 10 years or more. Patients do not become "immune" to levodopa, in a common myth they might encounter from nonauthoritative sources.

The worsening of consistent symptomatic control, as described above, is generally a problem of drug delivery that often can be improved on. Patients often ask about why PD sometimes appears as a cause of death in obituary listings, and a realistic explanation of why this is usually incorrect can be a comforting discussion to have. Because many PD patients are fortunate enough to have years (if not decades) of continuing symptomatic control, lack of progressive motor disability like imbalance, and avoidance of dementia, counseling should consider such a realistic appraisal. Certain subgroups of PD patients—those with resting tremor or predominantly unilateral presentations—are especially likely to have benign outcomes. It is also important for clinicians to share with patients that much of what is available to read about PD highlights the various problems of PD rather than how benign it can be.

A much-debated point in the treatment of PD is why declining efficacy can occur from continuing treatment with levodopa. End-stage PD can be denoted as an unfortunate state at which response to levodopa is inadequate for independent activities of daily living. Progression of the illness with further loss of dopamine storage sites in the presynaptic terminals is an unlikely explanation for this outcome because loss of these terminals in postencephalitic parkinsonism was reported to result in greater, not lower, sensitivity to levodopa.

Long-term studies have shown that, after 15 or more years, many PD patients encounter some form of disability (whether due to motor or nonmotor problems). The mortality rate at this stage of the illness exceeds that of an age-matched population. Despite very effective medications for the early symptoms of PD, problems of increasing bradykinesia, freezing of gait, postural disturbance, and retropulsive imbalance tend to predominate.

Falls leading to injuries becomes increasingly more common. Dysphagia with choking and aspiration, immobility with development of decubitus ulcers, and marked difficulty in communication capabilities are common events in very advanced PD. Dementia is at increasing risk to develop, along with psychosis, hallucinations, or paranoid ideation. As a result, placement in nursing homes often is necessary. Such a trajectory of the disease over time emphasizes the importance of better understanding the pathogenesis and the need for disease-modifying therapy.

Parkinson-Plus Syndromes 87

Paul Greene

KEY POINTS

1. Diseases that include a deficiency in dopamine share clinical features. The most common condition is Parkinson disease. The next most common conditions are progressive supranuclear palsy (PSP), multiple system atrophy (MSA), and corticobasal degeneration (CBD).
2. Some features that predict the pathology of PSP are supranuclear gaze palsy, lack of response to levodopa, early loss of balance, and/or freezing troubled and growling voice.
3. Some features that predict the pathology of MSA are combinations of scanning speech, ataxia and dysmetria, marked autonomic disturbances, and Parkinson features.
4. Some features that predict the pathology of CBD are apraxia, agnosia and cortical myoclonus, unilateral dystonia, and levodopa-unresponsive Parkinsonism.
5. The Parkinson features of PSP, CBD, and MSA usually do not respond to anti-Parkinson medications.
6. Some symptoms of PSP, MSA, and PSP can be treated, such as painful muscle cramps, apraxia of eyelid opening/blepharospasm, constipation, urinary disturbances, and depression.
7. Centrally acting medications that block the dopamine receptor or deplete dopamine can mimic the motor signs and symptoms of Parkinson disease.

INTRODUCTION

Parkinson disease (PD) is the most common cause for a dopamine deficiency syndrome, but other causes for this syndrome had been identified from a small number of pathologic examinations since the early 20th century. It was not until the introduction of levodopa to treat PD in the late 1950s and early 1960s that clinicians began to identify patients who had dopamine deficiency signs but, unlike patients with PD, had minimal or no improvement with levodopa. Because multiple causes for levodopa-unresponsive dopamine deficiency states were soon identified, such patients were said to have parkinsonism or Parkinson-plus syndromes. The three most common Parkinson-plus syndromes are progressive supranuclear palsy (PSP), multiple system atrophy (MSA), and corticobasal degeneration (CBD). In addition to these degenerative conditions, there are a number of other Parkinson-like conditions that also share clinical features with PD.

PARKINSON-PLUS SYNDROMES

Progressive Supranuclear Palsy

History

In 1964, Steele, Richardson, and Olszewski reviewed autopsies of patients who had a syndrome of pseudobulbar palsy, supranuclear ocular palsy (chiefly affecting vertical gaze), axial rigidity and dystonia, early loss of postural reflexes, and dementia. They found a pattern of neuronal degeneration and neurofibrillary tangles (NFTs), chiefly affecting the pons and midbrain. This condition became known as the *Steele-Richardson-Olszewski syndrome* or PSP. As more autopsies became available, it became clear that this characteristic pathology could also produce other patterns of initial symptoms in addition to the originally described disease now called *Richardson syndrome*. In progressive supranuclear palsy-parkinsonism (PSP-P), patients in the early stage of the disease resemble idiopathic PD. However, occasional patients with PSP pathology may also present with corticobasal syndrome (see the following text), progressive nonfluent aphasia (PNFA), akinesia with gait freezing, primarily ataxia, or even pure dementia.

Pathobiology

Atrophy of the dorsal midbrain, globus pallidus, and subthalamic nucleus; depigmentation of the substantia nigra; and mild dilatation of the third and fourth ventricles and aqueduct are seen on gross visual inspection of the postmortem brain in typical PSP. Light microscopy shows neuronal loss with gliosis, numerous NFTs, and neuropil threads in many subcortical structures, including the subthalamic nucleus, pallidum, substantia nigra, locus ceruleus, periaqueductal gray matter, superior colliculi, nucleus basalis, inferior olive, red nucleus, oculomotor nuclei, and cerebral cortex, especially the prefrontal and precentral areas. The NFTs appear as skeins of fine fibrils, often globose in shape in brainstem neurons. Ultrastructurally, they are composed of short, straight 12- to 15-nm tubules arranged in circling and interlacing bundles containing neurofilament proteins and the neurotubule-associated protein tau. In PSP, inclusion of exon 10 of tau creates a predominance of four repeated microtubule-binding domains, compared with a mixture of three and four repeated domains in Alzheimer disease. The typical astrocytic lesion in PSP is the tufted astrocyte, in contrast to the astrocytic lesion in CBD, the astrocytic plaque (see following text). Coiled bodies consisting of NFTs are found in astrocytes in both PSP and CBD (Fig. 87.1).

Symptoms and Signs

Patients with classical PSP or Richardson syndrome have an akinetic rigid Parkinson-like syndrome with early loss of postural

FIGURE 87.1 Pathology of progressive supranuclear palsy. The typical pathologic findings in progressive supranuclear palsy are tufted astrocytes (**A**), globose neurofibrillary tangle (*inset* in **A**), and coiled bodies (**B**). (Modified from Dickson DW. Neuropathology of non-Alzheimer degenerative disorders. *Int J Clin Exp Pathol.* 2009;3:1-23.)

reflexes, falls, and dementia and usually have a supranuclear palsy early in the course. Rest tremor, asymmetric onset, and improvement with levodopa are uncommon. Axial rigidity often exceeds limb rigidity, and the posture may be erect. Patients have facial dystonia with deep nasolabial folds and furrowed brow (Procerus sign), an appearance of surprise or concern. When the patient walks, the neck may be extended and the arms abducted at the shoulders and flexed at the elbows. Dysphagia and dysarthria usually appear early and become severe. The voice is slurred and sometimes hoarse or growling, and some patients become anarthric as the disease progresses. Gait "freezing" may be prominent, and transient arrest of motor activity interrupts walking, speaking, and/or other actions.

The first visual symptoms in Richardson syndrome are failure to maintain eye contact in social interactions and difficulty with tasks requiring downgaze, such as reading, eating, or descending stairs. Hesitation on voluntary downgaze is found on examination accompanied by loss of vertical opticokinetic nystagmus on downward movement of the target. Patients often complain of diplopia, blurred vision, or difficulty reading. Disturbances of eyelid motility are also common, including lid retraction (resulting in a staring expression), blepharospasm, and apraxia of eyelid opening or closing (inability to open or close the eyes to command despite normal strength and normal understanding of the command). Eyelid opening and closing apraxia (which are probably not true apraxia) are far more common in PSP than in any other extrapyramidal disorder. Fixation instability with coarse square-wave jerks and faulty suppression of the vestibulo-ocular reflex are common.

The cognitive impairment of PSP syndromes has been considered the archetype of subcortical dementia. The striking features are severe bradyphrenia (slowed thought), impaired verbal fluency, and difficulty with sequential actions or shifting from one task to another. Cognitive tests that depend on visual performance are especially affected. Apathy and disinhibition are common. Impulsiveness compounds postural instability and often leads to behavior that accentuates fall risk. Emotional incontinence is dominated by inappropriate weeping or, less frequently, laughing.

The course of PSP is aggressive; 3 to 4 years after onset, patients cannot walk without assistance and at a median of 5 years after onset, they are confined to bed and chair. They succumb to infection (from aspiration or pressure ulcers) or the sequelae of falls. The course varies according to the clinical syndrome, but Richardson syndrome has inexorable deterioration, culminating in death in 6 to 10 years in most cases.

In PSP-P, falls, dementia, and supranuclear palsy develop later, and patients are more likely to have an asymmetric onset, rest tremor, and response to levodopa early in the course (although these usually do not persist). In some patients with PSP pathology, depending on the distribution of pathology, language difficulty may precede motor signs, presenting as a dysarthric, slow expressive aphasia (called *primary progressive aphasia* or *progressive nonfluent aphasia*). In a small number of patients, variation in pathology may produce other initial syndromes: freezing and balance difficulty without significant rigidity (akinesia with gait freezing), pure dementia without significant motor deficits, cerebellar syndrome, or corticobasal syndrome (see the following text) (▶ Videos 87.1 and 87.2).

Multiple System Atrophy

History

It was noticed as early as 1900 that some patients with parkinsonian signs had additional signs and symptoms referable to other brain systems: cerebellar dysfunction (called *olivopontocerebellar atrophy* or OPCA) or autonomic dysfunction (termed *Shy-Drager syndrome* or SDS). Another syndrome of rapidly progressive parkinsonism with neuronal loss and gliosis primarily in the putamen and substantia nigra but no Lewy bodies on autopsy was termed *striatonigral degeneration* (SND). It was eventually noticed that some patients had elements of all these syndromes, and that patients with one clinical syndrome might have pathology overlapping with the other syndromes. The term *multiple system atrophy* was introduced to indicate that SND, SDS, and OPCA were all part of a single disease spectrum. The later identification of a common pathology (synuclein-containing glial cytoplasmic

TABLE 87.1 Clinical Forms of Progressive Supranuclear Palsy (PSP)[a]

Phenotype	Abbreviation	Description/Key Features
PSP-Richardson syndrome	PSP-RS	Vertical ocular motor dysfunction, early onset postural instability and falls
PSP-ocular motor	PSP-OM	Predominant ocular motor dysfunction
PSP-postural instability	PSP-PI	Predominant postural instability
PSP-parkinsonism	PSP-P	Clinical phenotype resembling Parkinson disease (later development of symptoms of PSP-RS)
PSP-frontal	PSP-F	Behavioral or frontal cognitive presentation (can be similar to behavioral variant frontotemporal dementia)
PSP-progressive gait freezing	PSP-PGF	Presentation with an isolated gait disorder with start hesitation and progressive freezing of gait
PSP-corticobasal syndrome	PSP-CBS	Corticobasal syndrome (one movement disorder sign and one cortical sign)
PSP-speech/language disorder	PSP-SL	Progressive apraxia of speech and/or nonfluent/agrammatic primary progressive aphasia
PSP-primary lateral sclerosis	PSP-PLS	Primary lateral sclerosis
PSP-cerebellar ataxia	PSP-C	Cerebellar ataxia as initial and predominant symptom

[a]From Armstrong M. Progressive supranuclear palsy: an update. *Curr Neurol Neurosci Rep*. 2018;18:12.

inclusions) confirmed the suspicion that these conditions represented one disease (Table 87.1). Some patients with MSA have upper motor neuron signs, and one of the original SDS patients had lower motor signs as well. It is not clear how many patients with parkinsonism and motor neuron disease have the pathology of MSA so that the current criteria for MSA do not include the parkinsonism-amyotrophy syndrome. Because most patients have some degree of autonomic dysfunction, the disease is now characterized according to the presenting motor dysfunction: MSA-parkinsonism when parkinsonism dominates the picture and MSA-cerebellar dysfunction when cerebellar dysfunction predominates.

Pathobiology

The full pathologic spectrum of MSA consists of neuronal loss and gliosis in the neostriatum, substantia nigra, globus pallidus, cerebellum, inferior olives, basis pontine nuclei, intermediolateral horn cells, corticospinal tracts, and, rarely, anterior horn cells. A characteristic pathologic feature is the presence of widespread glial cytoplasmic inclusions, particularly in oligodendroglia. These argyrophilic, α-synuclein–positive, perinuclear structures are primarily composed of straight microtubules containing ubiquitin and tau protein. In SND, nerve cell loss and gliosis are found predominantly in the substantia nigra and neostriatum. In SDS, the preganglionic sympathetic neurons in the intermediolateral horns are lost. In addition, other areas may be affected, particularly the substantia nigra (to produce parkinsonism), the cerebellum (to cause ataxia), and the striatum (to cause lack of response to levodopa). In OPCA, there is degeneration of the olives, pons, and cerebellum as well as neuronal loss in the striatum and substantia nigra. Less often, the anterior horn cells are involved (to cause amyotrophy) (Fig. 87.2).

Symptoms and Signs

The defining symptoms of SND are those of parkinsonism without tremor. Progression is usually rapid, and beneficial response to levodopa is absent or slight, presumably because striatal neurons containing dopamine receptors are usually lost.

FIGURE 87.2 Pathology of multiple system atrophy. The typical pathologic findings in multiple system atrophy are glial cytoplasmic inclusions (**A**), but they may be accompanied by neuronal inclusions (*arrow* in **B**) and α-synuclein–positive fibrillar neuronal inclusions (*inset* in **B**). (Modified from Dickson DW. Neuropathology of non-Alzheimer degenerative disorders. *Int J Clin Exp Pathol*. 2009;3:1-23.)

Dystonic reactions are common following low-dosage levodopa therapy. In these patients, sustained facial, neck, or limb contractions occur after exposure to levodopa. Orthostatic hypotension is a common presenting symptom of SDS syndrome (sometimes with labile blood pressure), but other dysautonomic symptoms are also troublesome, including impotence, urge incontinence, incomplete bladder emptying, and gastrointestinal motility disorders. Laryngeal stridor (often at night but sometimes during the day as well) strongly suggests SDS syndrome and can be life-threatening. Other sleep symptoms include dysrhythmic breathing, sleep, and central apnea. OPCA is characterized by a mixture of parkinsonism and cerebellar syndrome, including gait ataxia, dysmetria, scanning speech, nystagmus, hypometric saccades, supranuclear upgaze impairment, and other cerebellar eye movement abnormalities. The least common presentation of MSA involves amyotrophy mimicking amyotrophic lateral sclerosis (often combined with parkinsonism). Some patients with pathologic MSA may have pure autonomic failure for many years before developing other symptoms (and some may have the pathology and eventually develop symptoms of Lewy body disease). Dementia in MSA is rarely severe. As noted earlier, combinations of these symptoms often occur. Most patients progress rapidly and are in a wheelchair by a median 6 to 7 years after onset, although patients with cerebellar deficit predominance seem to progress more slowly. As in other Parkinson-plus syndromes, patients die from pulmonary, urinary tract and pressure ulcer infections, and complications of falls. Unlike the other syndromes, patients with MSA are also at risk for cardiopulmonary arrest due to autonomic dysfunction.

Corticobasal Degeneration

History

Initially reported as corticodentatonigral degeneration with neuronal achromasia in 1967, this disorder was characterized clinically by a combination of levodopa-unresponsive parkinsonism with early loss of balance, severe unilateral limb dystonia, and almost any focal cortical deficit. The pathology was also characteristic: enlarged achromatic neurons in cortical areas (particularly parietal and frontal lobes) along with nigral and striatal neuronal degeneration without Lewy bodies. The syndrome, also called *cortical-basal ganglionic degeneration* in the past, is now usually called *corticobasal degeneration*. As with PSP, it is now recognized that this pathology can also present clinically in other ways: as a frontal behavioral-spatial syndrome, PNFA, a PSP-like syndrome, dementia without motor abnormalities, or even as PD. Because patients with the pathology of PSP may mimic CBD, the original clinical syndrome is now called *corticobasal syndrome*. The overlap in both pathology and clinical features between CBD and PSP has raised concerns that the two diagnoses may represent a spectrum of a single disease despite a small number of pathologic findings unique to each diagnosis.

Pathobiology

In CBD, there is asymmetric atrophy usually most severe in the frontoparietal region with relative sparing of the occipital lobes. Swollen vacuolated neurons are found in the atrophic cortical areas and to a lesser degree in the affected subcortical regions. These swollen or ballooned neurons contain phosphorylated neurofilaments and sometimes tau and ubiquitin. There is neuronal loss and gliosis in affected cortex and in the globus pallidus, putamen, red nucleus, thalamus, subthalamic nucleus, substantia nigra, locus ceruleus, and to a lesser degree in the dentate nucleus. Remaining neurons in affected areas contain the globose tangles common in PSP, in this setting called *corticobasal bodies*. As in PSP, white matter is affected with a variety of abnormalities including tau-containing fibrils coiling around the nuclei of oligodendroglia (coiled bodies). The typical glial finding in CBD is not the tufted astrocyte common in PSP but tau-containing processes surrounding astrocytes called *astrocytic plaques*. As in PSP, four-repeat tau predominates, but the insoluble tau fragments in CBD have a different ultrastructure from the insoluble fragments of tau in PSP (Fig. 87.3).

FIGURE 87.3 Pathology of corticobasal degeneration. The typical pathologic findings in corticobasal degeneration are astrocytic plaques (clusters of tau-positive processes around a central astrocyte) **(A)**, ballooned neurons (*inset* in **A**), and threadlike processes **(B)**. (Modified from Dickson DW. Neuropathology of non-Alzheimer degenerative disorders. *Int J Clin Exp Pathol*. 2009;3:1-23.)

Symptoms and Signs

The onset of CBD is insidious and typically unilateral, with focal cortical deficits, and often marked rigidity—dystonia in the involved arm and/or leg. Sustained postures leading to contractures are common. Bradykinesia is usually present but may be hard to detect in the dystonic limb or limbs. Cortical signs of apraxia (inability to perform complex movements when comprehension and strength are intact), agnosia (inability to interpret complex sensory input even when primary sensation and comprehension are intact), alien limb phenomenon (when complex movements are performed by a limb out of the person's control), cortical sensory loss, cortical reflex myoclonus, and, occasionally, aphasia are usually dramatic. In addition to focal signs, global cortical dysfunction (dementia) is common. Speech is hesitant and dysarthric, gait is poor, and, occasionally, action tremor is evident. Falls usually occur shortly after onset of the disease. The disease usually spreads slowly to involve both sides of the body, and supranuclear gaze difficulties can occur late in the course. Patients with CBD pathology may present with several other syndromes. In the frontal behavioral-spatial syndrome, patients present with some combination of executive dysfunction, behavioral change, and visuospatial deficits. CBD at the onset may also look like PSP, PNFA, or a dementia without characteristic motor or focal cortical features (▶ Video 87.3).

EPIDEMIOLOGY

The reported prevalence of each syndrome varies dramatically. In part, this is because clinical studies tend to underestimate the prevalence, whereas autopsy studies tend to overestimate the prevalence (because unusual cases are more likely to come to autopsy). PSP is the most common, generally reported in clinical studies to have a prevalence of 1 to 20 per 100,000 (compared to 100-200 per 100,000 for PD). In a community-based study of 233 autopsies, 19% had PD, 3% had PSP, 0.9% had MSA, and 0.4% had CBD. Although PSP, CBD, MSA, and their syndromes are usually sporadic, recently a small number of rare genetic conditions were identified that may clinically resemble PSP, MSA, or CBD, including mutations in the genes *MAPT* and *PGRN* (for tau and progranulin), *C9orf72* (commonly causing familial amyotrophic lateral sclerosis and frontotemporal dementia), *TARDBP*, *CHMP2B*, and rare genetic mutations.

DIAGNOSIS

There have now been consensus criteria for the diagnosis of each of these syndromes. They were developed primarily for clinical research but are commonly used for clinical diagnosis as well (Tables 87.2-87.4).

Levodopa-unresponsive parkinsonism with early involvement of gait and balance suggests a Parkinson-plus syndrome, most commonly PSP, MSA, or CBD. Currently, dopamine transporter scans are available to detect a dopamine deficiency state, but the sensitivity is not known. There are two challenges: (1) Can we identify patients with signs and symptoms of one disease but the pathology of another? (2) Can we identify patients who seem to have idiopathic PD early in the course but actually have one of these syndromes?

It is not possible to predict the underlying pathology 100% of the time. Supranuclear vertical ophthalmoplegia suggests Richardson disease. Vertical eye movements are usually affected first in PSP, whereas eye movement problems develop late in CBD and are usually horizontal in MSA. Significant cerebellar deficits are most common in MSA but are rarely present in PSP. Autonomic failure is a hallmark of MSA and is uncommon in PSP and CBD but can be prominent in diffuse Lewy body disease (DLBD). Significant cognitive impairment is common in PSP and CBD but uncommon in MSA. Focal cortical deficits are a defining feature of CBD but occur in a minority of patients with PSP. Visual hallucinations and dopa-dyskinesias are more likely to be present in PD than in PSP-P or the other syndromes. Vascular parkinsonism often meets criteria for a Parkinson-plus syndrome and can be mistaken for PSP if eye movements are involved. Vascular parkinsonism can only be present with significant magnetic resonance imaging (MRI) abnormality, but white matter disease on MRI does not exclude PSP, MSA, or CBD. Frontotemporal lobar degeneration parkinsonism can mimic any of these conditions, especially if the dementia lags behind the motor symptoms.

PSP or CBD may present as dementia without motor abnormalities or as levodopa-responsive parkinsonism without incompatible signs and there may be no clinical way to correctly identify the disease until it progresses. Any patient with symmetric parkinsonian signs or where the lower body is more affected than the upper body may eventually develop a Parkinson-plus syndrome but this is neither sensitive nor specific.

^{18}F-fluorodeoxyglucose positron emission tomography (PET) can accurately distinguish between PD and all Parkinson-plus syndromes but is not generally available. There are other imaging markers for each of these syndromes but none is yet accepted as sensitive and specific. Midbrain atrophy can be quantified on computed tomography or MRI and is often different for PSP, MSA, and CBD. Rostral midbrain atrophy greater than pons atrophy may resemble the beak of a hummingbird in PSP. There may be hyperintensity in the dorsolateral margin of the putamen ("putaminal slit" sign) and cruciform increased signal in the pons ("hot cross bun" sign) in MSA. Focal cortical atrophy suggests CBD. Autonomic failure in MSA affects preganglionic sympathetic neurons (plasma epinephrine is normal when the patient is supine but fails to rise when the patient stands), and this may differentiate it from orthostasis in DLBD.

In the past, these syndromes were thought to be sporadic, but recently a small number of genetic conditions have been identified that may be clinically diagnosed as PSP, MSA, or CBD.

TREATMENT

The treatment of all Parkinson-plus syndromes is difficult, and the approaches are similar in PSP, CBD, and MSA and so are discussed together. Medications are usually ineffective for parkinsonian symptoms in these conditions but are more likely to be effective in MSA-cerebellar dysfunction when the striatum is relatively spared. Levodopa, however, can exaggerate orthostatic hypotension in MSA. Measures to overcome this problem include wearing support hose, ingesting salt, and taking fludrocortisone, midodrine, and other hypertensive agents. Patients can sleep with head elevated to avoid nocturnal hypertension and, if this is a problem, the dose of fludrocortisone should be kept to a minimum. If the striatum becomes more involved, with presumed loss of dopamine receptors, the benefit of levodopa diminishes. Treatment with levodopa requires increasing the dose to the maximum-tolerated dose or up to 2 g/d (in the presence of carbidopa) to determine whether any therapeutic

TABLE 87.2 Movement Disorder Society Diagnostic Criteria for Progressive Supranuclear Palsy[a]

Basic Features

1. Mandatory inclusion criteria	1. Sporadic occurrence 2. Age 40 y or older at onset of first PSP-related symptom 3. Gradual progression of PSP-related symptoms
2. Mandatory exclusion criteria	Clinical findings 1. Predominant, otherwise unexplained impairment of episodic memory, suggestive of AD 2. Predominant, otherwise unexplained autonomic failure, for example, orthostatic hypotension (orthostatic reduction in blood pressure after 3 min standing ≥30 mm Hg systolic or ≥15 mm Hg diastolic), suggestive of multiple system atrophy or Lewy body disease 3. Predominant, otherwise unexplained visual hallucinations or fluctuations in alertness, suggestive of dementia with Lewy bodies 4. Predominant, otherwise unexplained multisegmental upper and lower motor neuron signs, suggestive of motor neuron disease (pure upper motor neuron signs are not an exclusion criterion) 5. Sudden onset or stepwise or rapid progression of symptoms, in conjunction with corresponding imaging or laboratory findings, suggestive of vascular etiology, autoimmune encephalitis, metabolic encephalopathies, or prion disease 6. History of encephalitis 7. Prominent appendicular ataxia 8. Identifiable cause of postural instability, for example, primary sensory deficit, vestibular dysfunction, severe spasticity, or lower motor neuron syndrome Imaging findings 1. Severe leukoencephalopathy, evidenced by cerebral imaging 2. Relevant structural abnormality, for example, normal pressure or obstructive hydrocephalus; basal ganglia, diencephalic, mesencephalic, pontine or medullary infarctions, hemorrhages, hypoxic-ischemic lesions, tumors, or malformations
3. Context dependent exclusion criteria	Imaging findings 1. In syndromes with sudden onset or stepwise progression, exclude stroke, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) or severe cerebral amyloid angiopathy, evidenced by diffusion-weighted imaging (DWI), fluid-attenuated inversion recovery, or T2*-MRI 2. In cases with very rapid progression, exclude cortical and subcortical hyperintensities on DWI-MRI suggestive of prion disease. Laboratory findings 1. In patients with PSP-CBS, exclude primary AD pathology (typical CSF constellation [ie, both elevated total tau/phospho-tau protein and reduced β-amyloid 42] or pathologic β-amyloid PET imaging). 2. In patients aged younger than 45 y, exclude other causes of parkinsonism, such as Wilson disease, Niemann-Pick disease, neuroacanthocytosis, etc. 3. In rapidly progressive patients, exclude prion disease and paraneoplastic disease. 4. In patients with suggestive features (ie, gastrointestinal symptoms, arthralgias, etc.) exclude Whipple disease. Genetic findings 1. MAPT rare variants (mutations) are no exclusion criterion, but their presence defines inherited, as opposed to sporadic PSP. MAPT H2 haplotype homozygosity renders the diagnosis unlikely. 2. LRRK2 and Parkin rare variants have been observed in patients with autopsy-confirmed PSP, but their causal relationship is unclear so far. 3. Known rare variants in other genes are exclusion criteria because they may mimic aspects of PSP clinically but differ neuropathologically; these include non-MAPT associated FTD, PD, AD, and others.

Core Clinical Features

	Functional Domain			
Levels of Certainty	**Ocular Motor Dysfunction**	**Postural Instability**	**Akinesia**	**Cognitive Dysfunction**
High	O1: Vertical supranuclear gaze palsy	P1: Repeated unprovoked falls within 3 y	A1: Gait freezing within 3 y	C1: Speech/language disorder
Medium	O2: Slow velocity of vertical saccades	P2: Falls on pull-test within 3 y	A2: Levodopa resistant, akinetic-rigid	C2: Frontal cognitive/behavioral presentation
Low	O3: Frequent macro square wave jerks or "eyelid opening apraxia"	P3: Abnormal pull-test within 3 y	A3: Rest tremor and/or asymmetric and/or levodopa responsive	C3: Corticobasal syndrome

Supportive Features

Clinical Clues	Imaging Findings
CC1: Levodopa-resistance	IF1: Predominant midbrain atrophy or hypometabolism
CC2: Hypokinetic, spastic dysarthria	IF2: Postsynaptic striatal dopaminergic degeneration
CC3: Dysphagia	
CC4: Photophobia	

Abbreviations: AD, Alzheimer disease; CSF, cerebrospinal fluid; LRRK2, leucine-rich repeat kinase 2; MAPT, microtubule associated protein tau; MAPT H2, microtubule associated protein tau haplotype 2; MRI, magnetic resonance imaging; PET, positron emission tomography; PSP, progressive supranuclear palsy; PSP-CBS, progressive supranuclear palsy–corticobasal syndrome.

[a]Modified from Höglinger GU, Respondek G, Stamelou M, et al; for Movement Disorder Society-endorsed PSP Study Group. Clinical diagnosis of progressive

TABLE 87.3 Diagnostic Criteria for Multiple System Atrophy[a]

Possible MSA
Gradually progressive sporadic disease starting older than age 30 y
• At least one feature suggesting autonomic dysfunction:
◦ Unexplained urinary urgency, frequency, or incomplete bladder emptying
◦ Erectile dysfunction in males
◦ Significant orthostatic hypotension
• At least one additional feature of MSA (see in the following text)
• Either
◦ Parkinsonism (bradykinesia with rigidity, tremor, or postural instability)
◦ Cerebellar syndrome (gait ataxia with cerebellar dysarthria, limb ataxia, cerebellar oculomotor dysfunction)
Probable MSA
Gradually progressive sporadic disease starting older than age 30 y
• Autonomic failure with either
◦ Urinary incontinence (inability to control the release of urine from the bladder) with erectile dysfunction in men
◦ Orthostatic decrease of blood pressure within 3 min of standing by at least 30 mm Hg systolic or 15 mm Hg diastolic
• Either
◦ Poorly levodopa-responsive parkinsonism (bradykinesia with rigidity, tremor, or postural instability)
◦ Cerebellar syndrome (gait ataxia with cerebellar dysarthria, limb ataxia, cerebellar oculomotor dysfunction)
• Possible MSA-P or MSA-C
Additional Features of Possible MSA
◦ Babinski sign with hyperreflexia
◦ Stridor
• Possible MSA-P
◦ Rapidly progressive parkinsonism
◦ Poor response to levodopa
◦ Postural instability within 3 y of motor onset
◦ Gait ataxia, cerebellar dysarthria, limb ataxia, or cerebellar oculomotor dysfunction
◦ Dysphagia within 5 y of motor onset
◦ Atrophy on MRI of putamen, middle cerebellar peduncle, pons, or cerebellum
• Possible MSA-C
◦ Parkinsonism (bradykinesia and rigidity)
◦ Atrophy on MRI of putamen, middle cerebellar peduncle or pons
◦ Hypometabolism on FDG-PET in putamen
◦ Presynaptic nigrostriatal dopaminergic denervation on SPECT or PET

Abbreviations: FDG-PET, ^{18}F-fluorodeoxyglucose positron emission tomography; MSA, multiple system atrophy; MSA-C, MSA-cerebellar dysfunction; MSA-P, MSA-parkinsonism; MRI, magnetic resonance imaging; SPECT, single-photon emission computed tomography.

[a]Modified from Gilman S, Wenning GK, Low PA, et al. Second consensus statement on the diagnosis of multiple system atrophy. *Neurology*. 2008;71:670-676.

response can be obtained. Apraxia of eyelid opening (mainly in PSP) and painful dystonia or rigidity can be treated with botulinum toxin when the symptoms are relatively focal, and the muscles can be located and injected. Tricyclic antidepressants or dextromethorphan/quinidine may suppress inappropriate crying or laughing. Anticholinergic drugs in modest doses or botulinum toxin injections may be useful in controlling drooling. Patients with Parkinson-plus syndromes are at high risk for swallowing difficulty, so botulinum toxin should be used with care. Antidepressants may be helpful for depression in all Parkinson syndromes (it is not known if some antidepressants are more effective than others), although most patients do not tolerate dopamine receptor–blocking agents that are sometimes used to treat depression. 1-Deamino-8-D-arginine vasopressin at bedtime may help avoid nocturnal incontinence (and also help orthostasis). Constipation is managed as with idiopathic PD but may be less responsive to treatment. As with other Parkinson-plus syndromes, painful cramps may respond to botulinum toxin injections. Some families use enteric feeding when there is risk of aspiration. Gastric tubes do not prevent regurgitation followed by aspiration. Duodenal tubes do prevent aspiration but require continuous feeding, not bolus feeding (**Table 87.5**).

Recently, there has been a hypothesis that misfolded tau (in PSP and CBD) and misfolded α-synuclein (in MSA) may act like prions and cause the progression of these conditions. Studies are now underway to slow or stop the spread of these proteins inside the brain.

OTHER PARKINSON-LIKE SYNDROMES

Drug/Toxin-Induced Parkinsonism

Dopamine Receptor–Blocking Drugs

Drugs that block striatal dopamine D2 receptors (eg, phenothiazines, butyrophenones, thioxanthenes, and other centrally acting dopamine receptor blockers including some antinausea medications and some calcium channel blockers) or deplete striatal dopamine and serotonin (eg, reserpine, tetrabenazine) can induce a parkinsonian state. It may take weeks to months for the parkinsonism to resolve after the offending agent is withdrawn. Parkinsonism that persists longer than 6 months after drug withdrawal is attributed to underlying PD that became evident during exposure to these antidopaminergic drugs. Anticholinergic drugs can ameliorate drug-induced parkinsonian signs and symptoms. The atypical antipsychotic agents, clozapine, quetiapine, and more recently, pimavanserin, are the antipsychotics least likely to induce or worsen parkinsonism.

1-Methyl-4-Phenyl-1,2,3,6-Tetrahydropyridine

Although rare, parkinsonism induced by this toxin is important because it selectively destroys the dopamine nigrostriatal neurons, and the mechanism has been investigated intensively for possible clues to the etiology and pathogenesis of PD. 1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) is a protoxin, being converted to membrane palmitoylated protein 1 (MPP1) by the action of the enzyme monoamine oxidase type B. MPP1 is taken up selectively by dopamine neurons and terminals via the dopamine transporter system. MPP1 inhibits complex I in the mitochondria, depletes

TABLE 87.4 Diagnostic Criteria for Corticobasal Degeneration[a]

Probable CBD
• Insidious onset and gradual progression
• Onset on or after age 50 y, present for at least 1 y, less than two affected relatives
• Either
◦ Probable CBS
◦ FBS
◦ NAV with at least one probable CBS feature (see in the following text)
Probable CBS
Asymmetric presentation of both
• At least two of the following:
◦ Limb rigidity or akinesia
◦ Limb dystonia
◦ Limb myoclonus
• At least two of the following:
◦ Orobuccal or limb apraxia
◦ Cortical sensory deficit
◦ Alien limb (more than just overflow levitation)
FBS Syndrome
Two of the following:
• Executive dysfunction
• Behavioral or personality change
• Visuospatial deficits
Nonfluent/Agrammatic Variant of Primary Progressive Aphasia
Effortful, agrammatic speech with at least one of the following:
• Impaired grammar/sentence comprehension with relatively preserved single-word comprehension
• Groping, distorted speech production (apraxia of speech)
PSPS
Three of the following:
• Axial or symmetric limb rigidity or akinesia
• Postural instability or falls
• Urinary incontinence
• Behavioral change
• Supranuclear vertical gaze palsy or decreased vertical saccade velocity
Possible CBD
• Insidious onset and gradual progression
• Present for at least 1 y
• Either
◦ Probable CBS
◦ NAV or FBS
◦ PSPS with at least one possible CBS feature (see in the following text)
Possible CBS
Asymmetric or symmetric presentation of both
• At least one of the following:
◦ Limb rigidity or akinesia
◦ Limb dystonia
◦ Limb myoclonus
• At least one of the following:
◦ Orobuccal or limb apraxia
◦ Cortical sensory deficit
◦ Alien limb (more than just overflow levitation)

Abbreviations: CBD, corticobasal degeneration; CBS, corticobasal syndrome; FBS, frontal behavioral-spatial syndrome; NAV, nonfluent/agrammatic variant; PSP, progressive supranuclear palsy; PSPS, PSP syndrome.
[a]Modified from Armstrong MJ, Litvan I, Lang AE, et al. Criteria for the diagnosis of corticobasal degeneration. *Neurology*. 2013;80:496-503.

ATP, and increases the content of superoxide ion radicals. Superoxide in turn can react with nitric oxide to form the oxyradical peroxynitrite. MPTP-induced parkinsonism has occurred in drug abusers who used it intravenously and possibly also in some laboratory workers exposed to the toxin. The clinical syndrome is indistinguishable from PD and responds to levodopa. PET indicates that a subclinical exposure to MPTP results in a reduction of fluorodopa uptake in the striatum, thereby making the person liable to future development of parkinsonism.

Other Drugs Besides Dopamine Receptor Blockers and 1-Methyl-4-Phenyl-1,2,3,6-Tetrahydropyridine

Many other medications are occasionally reported to cause reversible parkinsonism, including antidepressants, anticonvulsants, antihypertensive medications, antiarrhythmics, immunosuppressants, and others. In some cases, parkinsonism is relatively common; in others, parkinsonism is reported only rarely. In the rare cases, other medications known to cause parkinsonism may have also played a role, and some may be coincidental idiopathic PD. For a partial list of drugs causing parkinsonism, see **Table 87.6**.

Lytico-Bodig (Parkinson-Dementia-Amyotrophic Lateral Sclerosis Complex of Guam)

Although not definitely a drug-induced disorder, epidemiologic evidence supports a probable environmental cause for Lytico-Bodig, with exposure occurring during adolescence or early adult years. Lytico-Bodig was identified when Chamorro natives on Guam in the Western Pacific were found to have a surprising incidence of parkinsonism, dementia, and motor neuron disease. The incidence has declined gradually with modernization of the culture. One hypothesis is that environmental exposure to the neurotoxin found in the seed of the plant *Cycas circinalis* was responsible for the neuronal degeneration. Natives on Guam used this seed to make flour in World War II. However,

TABLE 87.5 Treatment of Progressive Supranuclear Palsy, Multiple System Atrophy, and Corticobasal Degeneration

Indication	Treatment	Potential Side Effects
Motor difficulty	Sinemet to tolerance: Attempt to treat with 600-800 mg/d of levodopa per day if possible divided in three times a day dosing.	Orthostasis (esp. MSA), dystonia (esp. MSA), nausea, psychosis, others
Apraxia of eyelid opening (esp. PSP)	BTX-A injections: usually requires higher doses than used for blepharospasm, range of 25 100 units per eye. To achieve higher doses without ptosis, must concentrate the toxin to give higher dose without higher volume per injection site.	Ptosis, others
Depression	Antidepressants (except DRBA): same dose range per medication as for patients without parkinsonism	Lethargy, agitation, others
Drooling	Anticholinergics: as tolerated, usually very low doses (2-5 mg/d in this age group) BTX-B: varies dramatically from person to person, usually starting with 500 units per side and increase as tolerated if necessary	Dry mouth, confusion (anticholinergics), dysphagia (esp. BTX)
Nocturnal incontinence	DDAVP: 0.1 mg, 10 μg from 1 to 3 sprays per nostril each night at bedtime	Hypertension
Constipation	As with PD	—
Painful muscle cramps	BTX-A: usually very small dose per muscle is sufficient to reduce painful spasm, from 25-50 units per muscle depending on muscle size	Excess muscle weakness
Aspiration	Gastric or duodenal tube	—

Abbreviations: BTX, botulinum toxin; DDVAP, 1-deamino-8-D-arginine vasopressin; DRBA, dopamine receptor blocking agents; esp., especially; MSA, multiple system atrophy; PD, Parkinson disease; PSP, progressive supranuclear palsy.

TABLE 87.6 Drugs Causing Drug-Induced Parkinsonism[a,b]

Drugs/Indications	Mechanism of Action
High Risk of DIP	
First-generation antipsychotics: haloperidol, chlorpromazine, pimozide, thioxanthenes, trifluoperazine, others	Dopamine receptor blockade
Second-generation antipsychotics: risperidone, olanzapine, ziprasidone, aripiprazole	Dopamine receptor blockade
Dopamine depletors: tetrabenazine, valbenazine, deutetrabenazine, reserpine	Dopamine depletion
Antiemetics: metoclopramide, prochlorperazine	Dopamine receptor blockade
Ca^{++} channel blockers: flunarizine, cinnarizine	Dopamine receptor blockade
MPTP	Destruction of dopamine-producing neurons
Intermediate Risk of DIP	
Atypical antipsychotics: quetiapine, clozapine	Dopamine receptor blockade
Ca^{++} channel blockers: diltiazem, verapamil	—
Antiepileptics: valproic acid, phenytoin, levetiracetam	—
Mood stabilizers: lithium	—
Low Risk of DIP	
Antiarrhythmics: amiodarone	—
Immunosuppressants: cyclosporine	—
Antidepressants: SSRIs: fluoxetine, sertraline	—
MAO inhibitors: moclobemide, phenelzine	MAO inhibition
Antivirals: acyclovir, vidarabine, anti-HIV drugs	—
Statins: lovastatin	—
Antifungals: amphotericin B	—
Hormones: medroxyprogesterone, levothyroxine sodium	—
Cholinesterase inhibitors: donepezil, rivastigmine	—

Abbreviations: Ca^{++}, calcium ion; DIP, drug-induced parkinsonism; HIV, human immunodeficiency virus; MPTP, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine; MAO, monoamine oxidase; SSRIs, selective serotonin reuptake inhibitors.

[a]Reports of parkinsonism in the low-risk category may be contaminated by coincidental idiopathic Parkinson disease or by polypharmacy.

[b]Data from López-Sendón J, Mena MA, de Yébenes JG. Drug-induced parkinsonism. *Expert Opin Drug Saf.* 2013;12:487-496.

this hypothesis has been refuted. Besides parkinsonism, dementia, and motor neuron disease in various combinations, supranuclear gaze defects also appear. A characteristic pathologic finding is the presence of NFTs in the degenerating neurons, including the substantia nigra. Lewy bodies and senile plaques are absent.

Hemiparkinsonism-Hemiatrophy Syndrome

This relatively benign syndrome consists of hemiparkinsonism in association with ipsilateral body hemiatrophy and/or contralateral brain hemiatrophy. The parkinsonism usually begins in young adults and may remain as hemiparkinsonism, sometimes with hemidystonia, or progress to generalized parkinsonism. It tends to be nonprogressive or slowly progressive compared with PD. The disorder is thought to result from brain injury early in life, possibly even perinatally. It sometimes responds to medications.

Normal Pressure Hydrocephalus

The gait disorder in normal pressure hydrocephalus (see Chapter 110) resembles that of parkinsonism, with shuffling short steps and loss of postural reflexes and sometimes freezing. Features of urinary incontinence and dementia occur later. Tremor is rare. The grossly enlarged ventricles lead to the correct diagnosis, with the symptoms often improving on removal or shunting of cerebrospinal fluid. The gait disorder is in striking contrast to the lack of parkinsonism in the upper part of the body. The major differential diagnoses for lower body parkinsonism include vascular parkinsonism, Parkinson-plus syndromes, and even PD.

Parkinson-Dementia Syndromes

Although bradyphrenia is common in PD, dementia also occurs in about 30% of PD patients in clinics. The prevalence of dementia increases with age (affecting over 80% of patients with PD for 20 y), and those with dementia have a higher mortality rate. The two most common pathologic substrates for dementia in parkinsonism are pathologic changes typical of Alzheimer disease and the presence of Lewy bodies diffusely in the cerebral cortex. It is not known if the Alzheimer changes are coincidental because of the elderly population of affected individuals or whether Alzheimer disease and PD are somehow related. A clinical distinction has been made between patients who develop dementia before motor symptoms (or within a year of developing motor symptoms), labeled *DLBD* and those who develop dementia long after motor symptoms appear, labeled *Parkinson disease dementia*. Because these conditions are similar in most other pathologic and clinical features, it is not known if these represent the spectrum of one disease or multiple separate diseases. Similarly, it is not known whether the spread of Lewy bodies into the cortex is a feature of progression of PD or a distinct entity.

Postencephalitic Parkinsonism

Although rarely encountered today, postencephalitic parkinsonism was common in the first half of the 20th century. Parkinsonism was the most prominent sequel of the pandemics of encephalitis lethargica (von Economo encephalitis) that occurred between 1919 and 1926. Although the causative agent was never established, it affected mainly the midbrain, thus destroying the substantia nigra. The pathology is distinctive because of the presence of NFTs in the remaining nigral neurons and absence of Lewy bodies. In addition to slowly progressive parkinsonism, with features similar to those of PD, oculogyric crises often occurred in which the eyes deviate to a fixed position for minutes to hours. Dystonia, tics, behavioral disorders, and ocular palsies may be present. Patients with postencephalitic parkinsonism are more sensitive to levodopa, with development of dyskinesias, mania, or hypersexuality at low dosages. Anticholinergics are tolerated and are effective against oculogyria.

Vascular Parkinsonism

Vascular parkinsonism resulting from lacunar disease is not common but can be diagnosed by neuroimaging, with MRI evidence of hyperintense T2-weighted signals compatible with small infarcts. Hypertension is usually required for the development of this disorder. The onset of symptoms, usually with a gait disorder, is insidious, and the course is progressive. A history of a major stroke preceding the onset of parkinsonism is rare, although a stepwise course is sometimes seen. Gait is profoundly affected (lower body parkinsonism) with freezing and loss of postural reflexes. Tremor is rare. Response to the typical antiparkinsonian agents is usually minimal or absent.

Amyotrophic Lateral Sclerosis and Motor Neuron Diseases 88

Neil A. Shneider

KEY POINTS

1. Amyotrophic lateral sclerosis (ALS) is the most common adult-onset motor neuron disease, predominantly involving the degeneration of corticospinal, bulbar and spinal motor neurons.
2. ALS is a genetically complex disease for which pathogenic mutations have been identified in over 30 genes. Still, approximately 85-90% of ALS patients have no family history or known ALS gene mutation.
3. Common pathological features in the vast majority of ALS cases suggest shared underlying mechanisms of disease.
4. Clinical, pathological and genetic evidence links ALS to the related neurodegenerative disorder, frontotemporal dementia (FTD). Approximately half of all ALS patients have some degree of frontotemporal dysfunction.
5. Treatment for ALS largely remains supportive. Two FDA approved drugs for ALS—riluzole and edaravone—have a modest impact on the disease course.

INTRODUCTION

Motor neuron diseases comprise several disorders that are characterized primarily by the progressive degeneration of motor neurons in the spinal cord with or without the involvement of motor nuclei of the brainstem. *Motor neuron disease* is used to describe the typically adult-onset disease, *amyotrophic lateral sclerosis* (ALS), in which both corticospinal neurons, or "upper" motor neurons *and* lower motor neurons are affected. The terms *motor neuron disease* and *amyotrophic lateral sclerosis* are used interchangeably in the United States, where the disease is colloquially called *Lou Gehrig disease* after the famous baseball player who died of ALS in 1941. In Europe, ALS is named after Jean-Martin Charcot who first described the key clinical and pathologic features of the disease in 1869. As Charcot reported, ALS is predominantly a motor neuron disease, but clinical, genetic, and neuropathologic evidence have demonstrated that ALS is a multisystem neurodegenerative disorder, often associated with frontotemporal dementia (FTD), as described in Chapter 52.

The term *spinal muscular atrophy* refers to syndromes characterized solely by lower motor neuron signs. By conventional usage, the term *spinal muscular atrophy* is reserved for the childhood form, which is heritable, as described in Chapter 146.

TABLE 88.1 Motor Neuron Disease Variants

Amyotrophic lateral sclerosis (ALS)	Upper and lower motor neuron degeneration
Progressive muscular atrophy (PMA)	Purely lower motor neuron involvement
Primary lateral sclerosis (PLS)	Purely upper motor neuron involvement
Progressive bulbar palsy	Bulbar symptoms only or bulbar-onset ALS
Monomelic muscular atrophy	Lower motor neuron predominant, one arm
Bibrachial amyotrophy	Lower motor neuron predominant, both arms

Other motor neuron disease variants include progressive muscular atrophy (PMA), in which patients show only lower motor neuron signs; primary lateral sclerosis (PLS), in which only upper motor neuron signs; progressive bulbar palsy, in which weakness is limited to bulbar muscles; and monomelic amyotrophy, in which lower motor neuron findings are typically restricted to a single limb. These motor neuron disease subtypes are described more in detail in the following sections (Table 88.1).

It should be noted that there is some clinical overlap between motor neuron diseases, pure motor neuropathies (particularly those that are hereditary), and the hereditary spastic paraplegias (HSPs). Distinguishing and classifying clinical phenotypes that lie in the overlap between these diagnoses is often clinically challenging at present because of lack of diagnostic biomarkers.

Amyotrophic Lateral Sclerosis

ALS is defined pathologically as a disease in which there is degeneration of both *upper* motor neurons in the motor cortex and the *lower* motor neurons to which they project in the brainstem and spinal cord (Fig. 88.1). Clinically, ALS is defined by evidence of both lower motor neuron dysfunction (weakness, wasting, and fasciculation) and upper motor neuron dysfunction (spasticity, hyperactive tendon reflexes, or clonus) in the same limbs. There is no definitive test to establish a diagnosis of ALS, which remains a clinical diagnosis

FIGURE 88.1 Selective motor degeneration in amyotrophic lateral sclerosis. Degeneration of corticospinal neurons in the motor cortex leads to clinically apparent signs of upper motor neuron abnormalities: overactive tendon reflexes, Hoffmann signs, Babinski signs, and clonus. Degeneration of motor neurons in the brainstem and spinal cord causes muscle atrophy, weakness, and fasciculation. (From Rowland LP, Shneider NA. Amyotrophic lateral sclerosis. *N Engl J Med.* 2001;344[22]:1688-1700.)

based on the presence of upper and lower motor neuron signs in patients with progressive, painless muscle weakness in whom no alternative explanation is found.

EPIDEMIOLOGY

ALS has an annual incidence of approximately 2 to 3 per 100,000 and a prevalence of 10 to 12 per 100,000 in Europe and the United States. However, significant geographic differences exist; for example, the incidence of ALS in Asia is below 1 per 100,000 per year. Although considered rare, the estimated cumulative lifetime risk for developing ALS is 1 in 350 for men, and 1 in 400 for women. On average, the age of symptom onset varies between 58 to 63 years for sporadic disease and 40 to 60 years for familial ALS (fALS). Most commonly a disease of middle and late life, only 10% of ALS cases begin before age 40 years; 5% begin before age 30 years, with a greater proportion of younger cases associated with a pathogenic mutation in an ALS gene. There is no known ethnic predilection except slightly higher incidence in Norway because of the concentration of some genetic mutations.

Other than genetics, age, and male gender, no other factors have been identified in controlled studies that increase one's risk for ALS. The possible role of lifestyle choices (smoking, physical fitness, body mass index, and physical exercise), occupational and environmental exposures (electromagnetic fields, metals, pesticides, β-methylamino-L-alanine, and viral infection), and potential links between ALS and other medical conditions (head trauma, metabolic diseases, cancer, and inflammatory diseases) have been considered, but no causal relationship has been convincingly demonstrated.

PATHOBIOLOGY

Genetics

ALS is a genetically complex disease. Mutations in over 30 genes have been causally associated with ALS and the related neurodegenerative disorder, FTD. Approximately 5% to 10% of ALS cases are fALS—most often, inherited in an autosomal dominant pattern, although recessive and X-linked inheritance has been reported. In addition, because of de novo mutations, incomplete penetrance, or limited family history, pathogenic mutation are also found in a significant percentage of apparently "sporadic" cases of ALS. Mutations in known ALS genes account for approximately 60% of fALS cases in Europeans, but less than half of Asian fALS patients, and the genetic basis of these heritable cases of ALS still have to be identified (Fig. 88.2).

The most common, known cause of ALS is a mutation in the gene *C9orf72*. In 2011, an expansion of the GGGGCC hexanucleotide repeat in this gene was discovered and found to be responsible for 30% to 50% of fALS cases and 5% to 10% of sporadic disease in Europe. The mutation is less common in Asian patients (see Fig. 88.2). The *C9orf72* expansion is also the most common cause of FTD, and either or both of these clinical phenotypes occurs in individuals and families with this mutation.

Mutations in the gene encoding the enzyme superoxide dismutase 1 (*SOD1*) are the second most common genetic cause of ALS in Europeans, and the most common cause in Asia, accounting for 15% and 30% of fALS cases, respectively (see Fig. 88.2). In 1993, *SOD1* was the first ALS gene to be found, and over 150 pathogenic mutations have since been identified in this gene, associated with a range of clinical phenotypes. Although the molecular mechanisms by which mutant SOD1 causes neurodegeneration are not fully known, evidence from animal and cellular models and in vitro studies have shown that toxicity results from a gain of function, and not a loss of SOD1 activity. This suggested that selective gene silencing may be an effective therapeutic strategy for ALS patients with SOD1 mutations, and in 2015, clinical trials began to test the efficacy of an antisense oligonucleotide targeting the SOD1 transcript; similar efforts have begun for C9orf72, FUS, and other ALS-related genes.

A list of the currently identified mutations in fALS at the time of publication of this text are listed in Table 88.2.

Neuropathology

Neuropathologic examination of the brain and spinal cord of ALS patients reveals selective vulnerability of corticospinal neurons in layer V of the primary motor cortex and large-diameter (α) motor neurons in the brainstem and spinal cord. The pathologic hallmark of ALS is neuronal inclusions that include Bunina bodies—small eosinophilic intraneuronal inclusions—and ubiquitinated, skein, or dash-like aggregates. In the vast majority (>95%) of ALS patients, including cases of sporadic disease and heritable cases associated with mutations in *C9orf72* and *TARDBP*, as well as most other ALS-related genes, these cytoplasmic and neuritic inclusions are characterized by the presence of abnormally phosphorylated and ubiquitinated TAR DNA binding protein 43 (TDP-43), a DNA-/RNA-binding protein encoded by the gene *TARDBP* (Fig. 88.3).

FIGURE 88.2 Genetic architecture of familial amyotrophic lateral sclerosis (FALS) and sporadic amyotrophic lateral sclerosis (SALS) in European and Asian populations. (From Zou ZY, Zhou ZR, Che CH, Liu CY, He RL, Huang HP. Genetic epidemiology of amyotrophic lateral sclerosis: a systematic review and meta-analysis. *J Neurol Neurosurg Psychiatry*. 2017;88:540-549. doi:10.1136/jnnp-2016-315018.)

First implicated as a key histopathologic player in ALS and FTD of unclear significance to disease mechanism, rare mutations in *TARDBP* (TDP-43) were identified in 2008 that were causally associated with ALS and FTD, providing a genetic link between these clinically and pathologically related disorders, and implicating TDP-43 as an active mediator of neurodegeneration. Pathogenic mutations in *FUsed in Sarcoma* (*FUS*)—a gene encoding a DNA-/RNA-binding protein closely related to TDP-43—were subsequently identified in individuals and families with ALS, including cases of juvenile-onset disease characterized by rapid clinical progression, and distinct, FUS-positive neuronal cytoplasmic inclusions on neuropathologic examination. FUS immunoreactive inclusions are basophilic bodies, related but distinct from hyaline conglomerates, neuronal intermediate filament inclusions found in ALS and related forms of FTD. Rare *FUS* mutations and FUS pathology are also associated with a subtype of FTD with a distinct cognitive/behavioral phenotype (**Fig. 88.4**).

Another notable exception to the finding of TDP-43 pathology in ALS are those cases associated with *SOD1* mutations in which abnormal inclusions stain positive for SOD1. The role of these inclusions in the pathogenesis of ALS remain to be fully elucidated, but the common features of these cellular abnormalities found in all ALS subtypes, including phenotypic variants like PMA and PLS suggest a shared underlying mechanism for these motor syndromes as well as for FTD.

Genetic studies have provided important insight into the cause of ALS and related motor neuron disorders, but the molecular and cellular mechanisms that underlie neurodegeneration in ALS remain the subject of investigation. ALS-associated mutations in *TARDPB*, *FUS*, and other genes encoding ribonucleoproteins (eg, *hnRNPA1*, *TAF15*) suggest that defects in RNA metabolism represent key pathogenic mechanism. Combined with the genetic evidence, the prominence of these proteins in the histopathology of ALS in the absence of a genetic mutation suggest that these mechanisms are shared between sporadic and fALS. Mutations in genes encoding proteins involved in autophagy and other protein quality control pathways (eg, TBK1, OPTN, p62[SQSTM1], and possibly C9orf72) suggest that defects in proteostasis also contribute to the pathogenesis of ALS. ALS genes encoding proteins involved in cytoskeletal dynamics and axonal transport (eg, profilin 1 [PFN1], KIF5A, DCTN1, TUBA4A) have also implicated these processes in the pathobiology of ALS.

Amyotrophic Lateral Sclerosis and Frontotemporal Dementia

The clinical, pathologic, and genetic links between ALS and FTD have become increasingly obvious (see **Fig. 88.4** and Chapter 52). Approximately 50% of patients with ALS have some degree of frontotemporal dysfunction, which manifests in a variable degree of impairment of executive and language function and behavioral changes. In about 10% to 15% of ALS patients, criteria for behavioral variant FTD or primary progressive aphasia are met, and a diagnosis of ALS-FTD can be made. A growing number of genes have been causally associated with both ALS and FTD including *C9orf72*, *TARDBP* (TDP-43), *FUS*, *VCP*, *CHMP2B*, *hnRNPA1*, *CHCHD10*, *SQSTM1/p62*, *TBK1*, and *UBQLN2*. On neuropathologic examination, TDP-43 and FUS pathology are each observed in FTD as well as ALS patients.

TABLE 88.2 Amyotrophic Lateral Sclerosis–Associated Genes[a]

Name	Site	Gene	Inheritance	Comment
FTD-ALS	9p21	C9orf72	AD	ALS and FTD Hexanucleotide expansion Most common cause of ALS
ALS1	21q22.1	SOD1	AD	Adult 15%-20% of familial ALS
ALS2	2q33	Alsin	AR	Juvenile; may resemble PLS
ALS3	18q21	—	—	—
ALS4	9q34	Senataxin (SETX)	AD	Juvenile; slow progression; allelic to CMT2
ALS5	15q15.1-q21.1	SPG11	AR	Juvenile Most common AR ALS Also seen in HSP
ALS6	16p11.2	FUsed in Sarcoma (FUS)	AD	Adult and juvenile onset
ALS7	20p13	—	AD	Adult
ALS8	20q13.33	VAPB	AD	Adult
ALS9	14q11.2	ANG	AD	—
ALS10	1p36.22	TARDBP	AD	Some with FTD
ALS11	6q21	FIG4	AD	Allelic to CMT 4J (AR)
ALS12	10p13	OPTN	AD/AR	—
ALS13	12q24.12	ATXN2	AD	CAG expansions and increased ALS risk Expansions also seen with SCA2
ALS14	9p13.3	VCP	AD	Mutations also seen with IBMPFD
ALS15	Xp11.21	UBQLN2	X-linked	Reduced penetrance in women
ALS16	9p13.3	SIGMAR1	AR	Juvenile
ALS17	3p11.2	CHMP2B	AD	May cause FTD
ALS18	17p13.2	PFN1(Profilin 1)	AD	—
ALS19	2q34	ERBB4	AD	—
ALS20	12q13.13	HNRNPA1	AD	May cause multisystem proteinopathy
ALS21	5q31.2	MATR3	AD	Formerly distal myopathy 2, VCPDM
ALS22	2q35	TUBA4A	AD	ALS and FTD
ALS23	10q22.3	ANXA11	AD	
ALS24	4q33	NEK1	AD	
ALS25	12q13.3	KIF5A	AD	Adult Also seen in HSP

Abbreviations: AD, autosomal dominant; ALS, amyotrophic lateral sclerosis; AR, autosomal recessive; CAG, cytosine-adenine-guanine; CMT2, Charcot-Marie-Tooth hereditary neuropathy type 2; CMT4J, Charcot-Marie-Tooth neuropathy type 4J; FTD, frontotemporal dementia; HSP, hereditary spastic paraplegia; IBMPFD, inclusion body myopathy with Paget disease and frontotemporal dementia; PLS, primary lateral sclerosis; SCA2, spinocerebellar ataxia type 2; VCPDM, vocal cord and pharyngeal dysfunction with distal myopathy.

[a]Other genes described and implicated in familial ALS-DAO, NEFH, HNRNPA2B1, SQSTM1/p62.

CLINICAL MANIFESTATIONS

The clinical onset of ALS is variable. Patients are characterized by the site of symptom onset: **Bulbar onset** patients first have difficulty with speech or swallowing (dysarthria or dysphagia), whereas in those with **spinal onset** disease, weakness may begin in the upper or lower extremities. Respiratory insufficiency is often a late complication of disease but can also be an initial symptom in ALS patients. Axial muscle weakness and head drop are also common in later stages of disease but can be presenting symptoms. Clinical distinctions in ALS are also made on the basis of age of onset, rate of progression, the relative degree of upper versus lower motor neuron signs, and the presence or absence of nonmotor signs and symptoms, including frontotemporal dysfunction or pseudobulbar affect (PBA).

Progressive, painless weakness is the typical primarily clinical feature of ALS, which typically begins focally and "spreads" to contiguous anatomical regions (eg, right arm to left arm, or right arm to right leg). Often, the hands are affected first, usually asymmetrically, and with muscle atrophy (Fig. 88.5) and fasciculation, which occur as a result of spontaneous depolarization of a motor neuron and the synchronous contraction of all fibers of a single motor unit. Gait is impaired because leg muscles are weak, and foot drop is characteristic, although

FIGURE 88.3 TDP-43 positive cytoplasmic aggregates in spinal motor neurons in amyotrophic lateral sclerosis. A: Skeins: multiple string-like TDP-43–positive aggregates *(arrowhead)*. B: Dense round inclusions: These appear as dense, round TDP-43–positive aggregates *(arrowhead)*. (Scale bar = 10 μm.) (From Bodansky A, Kim JM, Tempest L, Velagapudi A, Libby R, Ravits J. TDP-43 and ubiquitinated cytoplasmic aggregates in sporadic ALS are low frequency and widely distributed in the lower motor neuron columns independent of disease spread. 2010;11[3]:321-327.)

FIGURE 88.5 Hand atrophy in amyotrophic lateral sclerosis.

proximal limb muscles are sometimes affected first. In upper motor neuron–predominant disease, a spastic gait disorder may be evident, as well as defects in motor control. Muscle cramps are sudden, painful, and involuntary contractions of a muscle associated with bursts of high-frequency (up to 150 Hz) firing of affected motor neurons. Weight loss is commonly seen in ALS as a result of muscle wasting, dysphagia and anorexia, but hypermetabolism—defined as a significant elevation in measured versus predicted resting energy expenditure—also contributes to weight loss in ALS. Respiratory impairment results from involvement of the diaphragm and accessory muscles of breathing. Dysphagia may lead to aspiration and pneumonitis, which are commonly fatal events for ALS patients. Typically, bowel and bladder continence and sexual function are preserved in ALS, attributed to the sparing of Onuf nucleus in the sacral spinal cord. Extraocular motor nuclei are also rarely affected in ALS, which accounts for the typical sparing of the muscles that control eye movement. No sensory loss is observed clinically unless an associated neuropathy is present. Pain is not a primary symptom in ALS but may occur when limbs are immobile due to severe spasticity and joint contracture.

FIGURE 88.4 Amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD) are related disorders that share a variety of genetic and cytopathologic features. While TDP-43 pathology is observed in the vast majority of ALS cases, SOD1 and FUS inclusions are found in ALS patients with causal mutations in the respective gene. TDP-43, FUS, and tau (MAPT) pathology are hallmarks of frontotemporal lobar degeneration in FTD patients. On the ALS-FTD spectrum, some genetic mutations cause ALS or FTD, but a number of these ALS-associated mutations also cause FTD in families and individuals—most notably, the hexanucleotide expansion in the C9orf72 gene. (Adapted from Ling SC, Polymenidou M, Cleveland DW. Converging mechanisms in ALS and FTD: disrupted RNA and protein homeostasis. *Neuron*. 2013;79[3]:416-438.)

Lower motor neuron signs must be evident if the diagnosis is to be considered valid. Fasciculations may be seen in the tongue, even without dysarthria. If there is weakness and wasting of limb muscles, fasciculations are almost always seen. Tendon reflexes may be increased or decreased; the combination of overactive reflexes with Hoffmann signs in arms with weak, wasted, and fasciculating muscles is virtually pathognomonic of ALS. Unequivocal signs of upper motor neuron disorder are spasticity, Hoffmann or Babinski signs, and clonus. If a spastic gait disorder is seen without lower motor neuron signs in the legs, weakness in the legs may not be found, but incoordination is evident by clumsiness and slowness in the performance of alternating movements (Table 88.3).

The cranial nerve motor nuclei are implicated by dysarthria, lingual wasting and fasciculations, and impaired movement of the uvula (Fig. 88.6). Facial weakness and wasting can be discerned, especially in the mentalis muscle, but is usually not prominent. Dysarthria and dysphagia caused by upper motor neuron disease is made evident by movements of the uvula that are more vigorous on reflex innervation than on volition; that is, the uvula does not move well (or at all) on phonation, but a vigorous response is seen in the pharyngeal or gag reflex.

Pseudobulbar palsy is an upper motor neuron palsy caused by loss of corticobulbar tract input to the cranial motor nuclei. Patients with pseudobulbar palsy have a lack of facial expression, difficulty chewing, and emotional lability (PBA). They present with upper motor neuron signs (spastic tongue, exaggerated gag, and

Facial weakness
Dysphagia
Dysarthria
Respiratory weakness
Neck weakness, head drop

jaw jerk reflexes), in contrast to patients with bulbar palsy who show lower motor neuron signs (atrophy and fasciculations of the tongue, absent gag reflex). PBA is a common nonmotor manifestation of ALS characterized by involuntary and uncontrollable laughter or crying that is disproportionate to an event. Episodes may also be mood incongruent in that a person may laugh uncontrollably when angry or frustrated, for example. PBA may often be misdiagnosed as clinical depression. Although not usually disabling as are the physical symptoms of ALS, PBA can have a negative social impact on one's interpersonal relationships, leading to isolation. Fortunately, symptoms of PBA respond well to a mixture of dextromethorphan hydrobromide and quinidine sulfate.

FIGURE 88.6 Tongue atrophy in amyotrophic lateral sclerosis.

DIAGNOSIS

ALS is primarily a clinical diagnosis and electrodiagnostic, radiographic, and laboratory test results must be combined with clinical finding to determine the diagnosis. Ultimately, a clinical history and a comprehensive physical and neurologic exam are the most important diagnostic tools in ALS evaluation. The combination of upper and lower motor neuron findings in multiple limbs with bulbar muscle involvement has little differential diagnosis.

Amyotrophic Lateral Sclerosis Diagnostic Criteria

Several sets of criteria have been proposed for the clinical and research diagnosis of ALS. The most commonly used are the revised El Escorial criteria (Table 88.4), which for the diagnosis of definite ALS, requires the combination of upper and lower motor neuron findings in three of four potential anatomic regions (cranial, cervical, thoracic, and lumbosacral). The Awaji ALS criteria were developed in 2008 with the intention of including a greater number of ALS patients earlier in their clinical course through some adjustments to the electrodiagnostic and clinical criteria required (Table 88.5). The Awaji criteria are primarily designed for research purposes, and many patients are diagnosed with and treated for ALS before they fully meet this standard.

Motor Neuron Disease Variants

ALS comprises multiple motor phenotypes that are mainly classified on the basis of the relative degree of upper versus lower motor neuron dysfunction and the regional distribution of clinical involvement.

Progressive Muscular Atrophy

PMA is the term used to describe the lower motor neuron only form of motor neuron disease. Clinical findings and course are similar to ALS but without the associated upper motor neuron signs, such as hyperreflexia, Babinski or Hoffman signs, or spasticity. Approximately 30% of patients diagnosed with PMA will develop upper motor neuron signs in the course of their disease, so pathologically true PMA likely accounts for less than 8% of cases of motor neuron disease. Patients with lower motor neuron–predominant ALS and PMA usually live longer than typical ALS patients.

TABLE 88.4 Revised El Escorial Criteria for the Diagnosis of Amyotrophic Lateral Sclerosis

• Suspected ALS: a pure LMN syndrome in two or more regions
• Possible ALS: UMN and LMN signs present together in one region or UMN signs alone in two or more regions or LMN signs rostral to UMN signs
• Laboratory-supported ALS: UMN and LMN signs in one region or UMN signs alone in one region with LMN signs identified by EMG in two regions
• Probable ALS: UMN and LMN signs in more than two regions, and some UMN signs must be rostral to (above) LMN signs
• Definite ALS: UMN and LMN signs in three or more regions
All require absence of electrophysiologic or pathologic evidence of another disease process to explain clinical findings.

Abbreviations: ALS, amyotrophic lateral sclerosis; EMG, electromyogram; LMN, lower motor neuron; UMN, upper motor neuron.

TABLE 88.5 Awaji Criteria for the Diagnosis of Amyotrophic Lateral Sclerosis

The diagnosis of amyotrophic lateral sclerosis (ALS) requires the presence of the following:
• Evidence of lower motor neuron (LMN) degeneration by clinical, electrophysiologic, or neuropathologic examination
• Evidence of upper motor neuron (UMN) degeneration by clinical examination
• Progressive spread of symptoms or signs within a region or to other regions, as determined by history, physical examination, or electrophysiologic tests
The absence of the following:
• Electrophysiologic or pathologic evidence of other disease processes that might explain the signs of LMN and/or UMN degeneration
• Neuroimaging evidence of other disease processes that might explain the observed clinical and electrophysiologic signs
Diagnostic Categories
• Clinically definite ALS is defined by clinical or electrophysiologic evidence by the presence of LMN as well as UMN signs in the bulbar region and at least two spinal regions or the presence of LMN and UMN signs in three spinal regions.
• Clinically probable ALS is defined on clinical or electrophysiologic evidence by LMN and UMN signs in at least two regions with some UMN signs necessarily rostral to (above) the LMN signs.
• Clinically possible ALS is defined when clinical or electrophysiologic signs of UMN and LMN dysfunction are found in only one region, or UMN signs are found alone in two or more regions, or LMN signs are found rostral.

The diagnosis of PMA should always be made with caution because it raises the question of a potentially treatable motor neuropathy, such as multifocal motor neuropathy (MMN). Diagnostic testing should include electrodiagnostic testing (electromyography and nerve conducting studies) with proximal stimulation on nerve conduction studies (NCS) to exclude areas of conduction block and demyelinating findings, lab testing to evaluate for antibodies often seen in motor neuropathies, and consideration for spinal fluid testing to look for elevated protein. Magnetic resonance imaging (MRI) of the brain and transcranial magnetic stimulation (TMS) can be used to look for subclinical upper motor neuron involvement.

Primary Lateral Sclerosis

PLS refers to the clinical syndrome of progressive motor neuron disease affecting only upper motor neurons. Typically, symptoms of PLS begin symmetrically in the legs, but bulbar onset disease is also common. For a diagnosis of PLS, no lower motor neuron signs (muscle atrophy, visible fasciculations, or electrophysiologic evidence of denervation) can be present. A majority of PLS patients develop lower motor neuron signs within 3 to 4 years of disease onset, and the clinical picture becomes one of upper motor neuron–predominant ALS. PLS represents only about 3% to 5% of all cases of motor neuron disease.

The clinical symptoms and signs in PLS include spasticity and associated gait dysfunction, spastic dysarthria, and associated pathologic reflexes. Testing must include neuroimaging to exclude structural causes of upper motor neuron injury, lab testing to evaluate for metabolic disorders mimicking the clinical picture, and consideration for spinal fluid testing for infectious and inflammatory causes. Electrodiagnostic testing is critical for evaluating for lower motor neuron involvement, even in patients without clinical atrophy or fasciculations, and may need to be repeated over months to years to confirm the absence of denervation. The appearance of lower motor neuron signs can be delayed in some patients initially diagnosed with PLS, whose disease morphs into an upper motor neuron–predominant form of ALS. For this reason, a diagnosis of PLS requires at least 4 years of observation. When spasticity and upper motor neuron findings are restricted to the legs or spare bulbar muscles, the clinician must consider the alternative diagnosis of hereditary spastic paraplegia.

Progressive Bulbar Palsy

The term *progressive bulbar palsy* has been used to describe motor neuron disease selectively affecting the bulbar muscles, causing dysarthria and dysphagia. This term is falling out of favor because most of these patients do have at least some limb involvement, which may be subclinical at the time that bulbar symptoms begin. The term *bulbar-onset ALS* is more appropriate to describe those patients presenting with early or prominent bulbar symptoms.

Monomelic Muscular Atrophy

Monomelic muscular atrophy is a focal motor neuron disease restricted to one limb, usually an arm and a hand rather than a leg. Other names for the syndrome include *monomelic amyotrophy*, *benign focal amyotrophy*, *spinal muscular atrophy of the unilateral upper extremity*, and *Hirayama syndrome*.

Monomelic muscular atrophy affects men 10 times more often than women and starts at about 20 years of age, in contrast to typical sporadic ALS, which has a much older age of onset. The disease is most commonly seen in southeastern Asia, particularly in Japan and India, although cases have been reported in Western countries. The weakness typically involves the hand and forearm, involving C7-T1 innervated muscles. Tendon reflexes are generally reduced in the affected arm. Upper motor neuron signs in other limbs are not seen. The condition progresses for 1 or 2 years and then seems to become arrested in most cases, although some patients continue to progress slowly for many years. The origin of the disorder is not known.

A *pseudopolyneuritic* variant of ALS, also known as *flail leg syndrome*, is also a lower motor neuron–predominant disorder characterized by progressive, asymmetrical, distal-onset weakness and wasting in the lower extremities, without initial involvement of the upper extremities or bulbar region. Compared to typical ALS, patients with monomelic syndromes have a significantly longer expected survival after symptom onset.

The differential diagnosis for monomelic muscular atrophy should include the initial onset of a more generalized ALS, MMN, or polio-like infectious syndromes, as in those seen with West Nile virus.

Bibrachial Amyotrophy

A few percent of patients develop a lower motor neuron syndrome restricted to both arms. As in monomelic amyotrophy, it is more common in men than women, with a ratio of 8 to 9:1. It usually presents with proximal arm and shoulder muscle weakness. The progression is much slower than typical ALS. Arm posture is typically pronated, and arms are dangling; sometimes, it is called *brachial amyotrophic diplegia* or *man-in-the-barrel syndrome*. Usually, lower motor neuron findings predominate, but, sometimes, upper motor neuron signs are present.

Diagnostic Testing

Electrodiagnostic Testing

Electrodiagnostic testing including NCS and EMG are critical to demonstrating lower motor neuron involvement in ALS and excluding motor neuropathy mimics. NCS may not only show low motor amplitudes but may also be normal, particularly early in the disease course. NCS are done primarily to exclude findings suggestive of motor neuropathy, with conduction block or other demyelinating features. Abnormal sensory responses should not be seen in ALS unless related to an unrelated condition (eg, diabetic neuropathy). Needle EMG should demonstrate evidence of active denervation (fibrillation and fasciculation potentials) and chronic denervation in three body segments (cranial, cervical, thoracic, and lumbosacral) to meet Awaji or El Escorial criteria. It should be noted that the electrodiagnostic testing must be combined with radiographic data and finding on clinical exam because a severe polyradiculopathy or motor neuropathy could cause similar EMG abnormalities.

TMS is an electrodiagnostic method used to assess central nerve conductions as a functional measure of upper motor neuron abnormalities in ALS. TMS is most useful when the predominant clinical picture is of lower motor neuron dysfunction, which may mask upper motor neuron findings. Stimulation over the motor cortex, cervical spine, and lumbar spine is performed with recording of a compound motor action potential, assessing for delayed latency, and central conduction. TMS is not widely available.

Neuroimaging

Imaging of the brain and spine, with MRI is typically recommended to exclude structural processes, including mass lesions and degenerative spine disease that may mimic the signs and symptoms of ALS. In most cases of ALS, neuroimaging is normal or demonstrates mild incidental abnormalities; however, occasionally, MRI shows abnormally high-signal intensity in the intracranial corticospinal tract on T2-weighted and proton density–weighted images and fluid-attenuated inversion recovery sequences. Although the relationship of these abnormalities to upper motor neuron dysfunction are not clear, hyperintensity in the corticospinal tract is diagnostic evidence in support of upper motor involvement in ALS, especially when found in the subcortical precentral gyrus, centrum semiovale, and cerebral peduncles levels. MRI evidence of atrophy in frontal and temporal regions is evidence of associated FTD in ALS patients.

Lab Testing

Spinal fluid studies are not required in the assessment of a patient with suspected ALS. However, in atypical cases, lower motor neuron (PMA) or upper motor neuron variants (PLS), or when there is concern for a motor neuropathy mimic, these studies should be done to look for elevation in protein, white blood cells, abnormal cytology, or elevated immunoglobulin G synthesis.

Blood tests are recommended to evaluate for metabolic, endocrine, or inflammatory conditions that might mimic ALS. Testing for monoclonal gammopathy, antiganglioside antibodies, angiotensin-converting enzyme levels, parathyroid hormone, and paraneoplastic markers rarely result in an alternative diagnosis. Creatine kinase levels are often modestly elevated in ALS and are not inconsistent with the diagnosis. As gene silencing and other targeted therapeutics are developed for genetic forms of ALS, and given the implications for family members at risk, genetic testing for ALS-associated mutations should be considered in all cases of ALS, including those in which no family history is suggested. This is best performed with the help of a genetic counselor or physician experienced in genetic testing.

Muscle Biopsy

Muscle biopsy is not routinely recommended in the evaluation of ALS and associated motor neuron disorders and typically demonstrates findings consistent with active and chronic denervation. The primary indication for muscle biopsy when considering a diagnosis of ALS is if there are clinical findings suggestive of inclusion body myositis (IBM), which may have some overlap in clinical presentation.

Differential Diagnoses

Although the typical clinical picture of ALS is difficult to confuse with other neurologic disorders, cases occur that raise the question of other neuromuscular disorders with similar clinical phenotypes. Given that there is currently no disease-modifying treatment for ALS, the focus of testing when this diagnosis is considered is on excluding these other potentially treatable disorders (Table 88.6).

Multifocal Motor Neuropathy

MMN or MMN with conduction block is a clinical syndrome of pure motor neuropathy, with conduction block in more than one nerve and not at sites of entrapment neuropathy. Anti-GM1 or other ganglioside antibodies are often associated. Symptoms often begin or predominate in the upper extremities. Although frank upper motor neuron findings should not be present, deep tendon reflexes are sometimes relatively preserved and muscle atrophy is often minimal given the degree of weakness. MMN is a potentially treatable autoimmune condition, treated with intravenous immunoglobulin or other immunosuppressing drugs, so the focus of NCS is often on assessing for this treatable diagnosis.

Myasthenia Gravis

Myasthenia gravis is a common cause of dysarthria and dysphagia in people who are in the age range of those afflicted with ALS and may be considered in the differential diagnosis when bulbar symptoms predominate. If there is concomitant ptosis or ophthalmoparesis, if diurnal fluctuation in severity is marked, or if remissions have occurred, myasthenia gravis is more likely. If there is suspicion for this diagnosis, testing should include blood testing of antibodies to acetylcholine receptor and muscle-specific tyrosine kinase and repetitive stimulation with NCS. Myasthenia gravis is reviewed further in Chapter 93.

Spinal Stenosis

Although spinal disease should not cause bulbar symptoms, cervical and lumbosacral polyradiculopathy due to spinal stenosis can cause a combination of upper and lower motor neuron symptoms and exam findings in patients with pure limb symptoms, which may be difficult to distinguish from limb-onset ALS. Spine imaging with MRI is thus recommended for all patients in whom the diagnosis of ALS is considered. Spinal stenosis is reviewed further in Chapter 114.

Myopathy

Myopathy, most notably IBM, may present with a clinical syndrome similar to ALS, with prominent arm weakness (typically affecting finger flexors and quadriceps disproportionately) and

TABLE 88.6 Differential Diagnosis of Motor Neuron Diseases

Multifocal motor neuropathy	• Primarily lower motor neuron syndrome but may have preserved reflexes • Conduction block on nerve conduction studies • Lab testing for GM1 antibodies
Chronic inflammatory demyelinating polyneuropathy	• Sensorimotor involvement is clinically typical. • Demyelinating findings on nerve conduction studies • Elevated CSF protein
Myasthenia gravis	• Ocular symptoms, fluctuation, and fatigability are more typical. • Decrement on repetitive stimulation with nerve conduction studies and no denervation on needle EMG • Acetylcholine receptor and muscle-specific kinase antibodies if clinically appropriate
Spinal stenosis	• Typically more pain and sensory symptoms • MRI or other imaging demonstrates structural abnormalities • No bulbar or facial involvement
Inclusion body myositis	• Typically affects quadriceps and finger flexors more severely • Needle EMG shows myopathic findings. • Greater elevations in CK levels • Muscle biopsy to confirm diagnosis if clinical suspicion
Postpolio syndrome	• History of polio with later life decline in strength
Hereditary spastic paraparesis	• Upper motor neuron syndrome affecting primarily the legs • Family history may be useful. • Genetic testing when clinically appropriate
Benign fasciculation syndrome/cramp fasciculation syndrome	• Absence of weakness, muscle wasting • Electrodiagnostics may show fasciculations but no other abnormalities.
Paraneoplastic syndromes	• Paraneoplastic panel/antibody testing
Other systemic disorders	• Diabetes, sarcoidosis, parathyroid disease, hexosaminidase A deficiency

Abbreviations: CK, creatine kinase; CSF, cerebrospinal fluid; EMG, electromyogram; MRI, magnetic resonance imaging.

bulbar symptoms. Needle EMG testing is usually suggestive of a myopathic disorder, but, sometimes, neurogenic findings are seen. Creatine kinase levels should be higher in IBM than in ALS. Fasciculations and upper motor neuron findings should not be seen in muscle disorders. Muscle biopsy is recommended when inflammatory myopathies are considered.

Postpolio Syndrome

Postpolio syndrome is characterized by clinical worsening of weakness years after full or partial recovery from viral poliomyelitis. This syndrome is likely a consequence of the slow loss of anterior horn cells with normal aging in postpolio patients who previously lost a large fraction of motor neurons in certain motor pools. The function of these previously paralyzed muscles depends on the giant motor units that result from the reinnervation of denervated muscle fibers through terminal axonal sprouting during the recovery phase of acute polio. As these units degenerate with age, new weakness progresses slowly in these previously paralyzed muscles.

Benign Fasciculations

Fasciculations, with or with muscle cramps, in the absence of weakness or upper motor neuron findings is nearly always a benign finding. There is no increased risk for future motor neuron disease in these patients. Electrodiagnostic testing may be useful to demonstrate no evidence of active or chronic denervation and to reassure the patient regarding the diagnosis.

Spinobulbar Muscular Atrophy (Kennedy Disease)

Although not considered a form of fALS, X-linked recessive spinobulbar muscular atrophy (SBMA), commonly known as *Kennedy disease*, is a hereditary motor neuron disease that should be included in the differential diagnosis of ALS. SBMA is a progressive debilitating neurodegenerative disorder resulting in muscle cramps and progressive weakness due to degeneration of motor neurons in the brainstem and spinal cord. SBMA is caused by expansion of a trinucleotide cytosine-adenine-guanine (CAG) repeat in the first exon of the androgen receptor gene, which maps to Xq11-q12. Early symptoms often include dysarthria and dysphagia with prominent tongue and mentalis fasciculations. Increasing weakness of limb muscles with muscle wasting gradually ensues. Upper motor neuron signs are often absent. In contrast to ALS, there is often an associated large-fiber sensory peripheral neuropathy. Gynecomastia is present in most but not all patients. Diagnostic clues include the characteristic distribution of signs, lack of upper motor neuron signs, slow progression, and a family history suggesting X-linked inheritance. Symptoms usually begin after age 40 years, and the disease progresses very slowly but can eventually lead to extreme disability. Earlier symptom onset and increased severity of the disease correlate with the length of the expansion of the CAG repeat. Neuromuscular management is supportive.

MANAGEMENT

Pharmacotherapy

Despite advances in our understanding of ALS genetics and the mechanisms that underlie neurodegeneration, there is no effective disease-modifying drug therapy for ALS or related motor neuron diseases.

Riluzole, a glutamate inhibitor, was the first drug approved by the U.S. Food and Drug Administration (FDA) for the treatment of ALS. In two randomized controlled trials, it was shown to improve 12- and 18-month survival, although the benefits were small LEVEL 1.[1,2] The usual dose is 50 mg twice daily. The most common side effects are nausea and dizziness, and hepatic function monitoring is recommended.

Edaravone (Radicava) was approved for the treatment of ALS in Japan in June 2015 and by the FDA in May 2017. Administered by intravenous infusion, edaravone is known to be an antioxidant, but the mechanism by which it might be effective in ALS is unknown.

Multidisciplinary Supportive Care

Given the limited efficacy of pharmacotherapy, treatment is primarily symptomatic (Table 88.7). Management by a multidisciplinary ALS care center is one of the few interventions

TABLE 88.7 Treatment for Amyotrophic Lateral Sclerosis and Motor Neuron Disorders

Disease Modifying
• Riluzole: only FDA-approved disease-modifying therapy for ALS
Improving Quality of Life and/or Survival
• Multidisciplinary ALS center care
• Noninvasive positive pressure ventilation/cough assist machine
• Physical therapy and rehabilitation
• Durable medical equipment and assistive devices to prevent falls and improve mobility
• Nutritional/calorie maintenance and percutaneous gastrostomy tube
• Tracheostomy and mechanical ventilation
Symptomatic Therapies
• Treatment of sialorrhea—atropine, glycopyrrolate, amitriptyline, botulinum toxin injections
• Treatment of spasticity—baclofen, cyclobenzaprine, benzodiazepines, intrathecal baclofen
• Communication devices
• Pseudobulbar symptom management—dextromethorphan-quinidine, SSRIs
• Treatment of depression and associated mood disorders—SSRI, SNRI, tricyclic antidepressants
• Treatment of fatigue—modafinil, pyridostigmine
• Emotional support for patient and family caregivers
Comfort Measures, Pain Control, Palliative Care, and Hospice

Abbreviations: ALS, amyotrophic lateral sclerosis; FDA, U.S. Food and Drug Administration; SNRI, serotonin-norepinephrine reuptake inhibitors; SSRIs, selective serotonin reuptake inhibitors.

shown to improve survival and quality of life LEVEL 2.[3] Early in the course, patients should try to continue to perform routine activities as long as they can. There is difference of opinion about exercising weak muscles, but physical therapy can help maintain function as long as possible. Drooling of saliva (sialorrhea) may be helped by atropine sulfate, glycopyrrolate, amitriptyline, or botulinum toxin injections into the salivary glands. Antispasticity agents are of limited use in the treatment of spastic gait disorder, but intrathecal administration of baclofen might be considered in some patients, particularly those with PLS and upper motor neuron–predominant ALS. Dysphagia often leads to the placement of a feeding tube to maintain nutrition and hydration, but it does not prevent aspiration. Augmentative communication devices are used to support patients with severe dysarthria/anarthria. Noninvasive positive pressure ventilation has been used with increasing frequency to manage nocturnal dyspnea, insomnia, and overall respiratory discomfort, and it is likely not only to prolong life but also to improve quality of life LEVEL 2.[4] Use of a mechanical in-exsufflation or cough assist device together with noninvasive positive pressure ventilation can also have a positive effect on patients' survival. Medications may also help with pseudobulbar symptoms, including the use of the combination drug dextromethorphan-quinidine LEVEL 2.[5]

The long-term care of patients with ALS has been addressed by evidence-based medicine recommendations made by a committee of the American Academy of Neurology. These guidelines state that management by a multidisciplinary ALS care team results in better symptomatic treatment, improved quality of life, and prolonged survival. Advance care planning is an important aspect of disease management. In Western countries, only a minority of ALS patients undergo tracheostomy and mechanical ventilation, and such interventions commonly occur under emergency conditions in the absence of advance directives. Palliative care medicine—a practice focused on treating the symptoms, discomfort and stress of illness, an on giving physical and emotional support to patients and families—has become a standard of ALS care (see also Chapter 158).

OUTCOME

The natural history of ALS is highly variable, so it is not possible to predict disease course and outcome accurately in individual patients. This complicates risk assessment and counseling of those newly diagnosed with ALS as well as the stratification of patients in clinical trials. For the ALS patient population as a whole, certain clinical features of the disease are associated with shorter survival, including bulbar and respiratory onset, advanced age at onset of symptoms, and a rapid functional decline (as measured by the ALS functional rating scale revised). Based on these determinants, a predictive model of survival has been developed for individual patients with ALS, which may serve as useful tools for personalized patient management, counseling, and innovative trial design. As noted, some specific ALS-related mutations are also associated with rapid progression and reduced survival (eg, A4V in *SOD1* and P525L in *FUS*). In general, the course is progressive without remission or stable plateaus. Death typically results from respiratory failure, aspiration pneumonitis, or pulmonary embolism after prolonged immobility. The mean duration of symptoms is about 4 years; nearly 10% of patients live longer than 10 years. Once a tracheostomy has been placed, the patient may be kept alive for years, although paralyzed except perhaps for eye movement. In exceptional cases, patients die in the first year or live longer than 25 years.

Bell's Palsy and Cranial Neuropathies 89

Comana M. Cioroiu and Thomas H. Brannagan III

KEY POINTS

1. Cranial neuropathies can occur together (as in cases of cancer, infarct, and central nervous system inflammatory diseases) or in isolation.
2. Loss of olfactory sensation can be caused by either congenital or acquired causes and is typically accompanied by loss of taste and appetite.
3. Trigeminal neuralgia is a syndrome of extremely severe facial pain characterized by recurrent paroxysms of sharp stabbing pains in the distribution of one or more nerve branches and is treated first line with carbamazepine. Glossopharyngeal neuralgia is a clinically similar entity affecting the sensory distribution of the ninth cranial nerve.
4. Central lesions of the facial nerve above the level of the facial nucleus cause weakness of the lower face with sparing of forehead muscles.
5. Lesions of the nerve peripherally (at or below the level of the nucleus) cause weakness of the entire ipsilateral face and depending on the location of the lesion may also include a loss of taste, salivation, and lacrimation.
6. Steroids should be offered to patients with Bell's palsy within 72 hours of symptom onset, and prognosis is typically very favorable.
7. Reactivation of a latent varicella-zoster virus infection in the geniculate ganglion leads to inflammation of the facial nerve and Ramsay Hunt syndrome, in which facial pain is common.
8. The vagus nerve (cranial nerve X) has a parasympathetic efferent pathway, a motor efferent pathway to the larynx and pharynx, and afferent pathways.
9. Unilateral injury to the hypoglossal nucleus causes atrophy and paralysis of the muscles of half the tongue causing deviation toward the paralyzed side upon protrusion.

INTRODUCTION

Isolated cranial neuropathies are not uncommon, the most frequently encountered of which is Bell's palsy. These syndromes can be seen in both the inpatient and outpatient settings, and all have a very varied differential diagnosis. The cranial nerve examination is a crucial component of a complete neurologic exam. Cranial nerve injury can be implicated in various diseases with widespread neurologic involvement such as stroke, multiple sclerosis, and demyelinating neuropathies, particularly when other pathways and neuroanatomic regions are involved as well. Cranial neuropathies can occur together (with involvement of more than one nerve) or in isolation (with involvement of only one nerve). Multiple cranial neuropathies are most often caused by cancer, central nervous system (CNS) inflammatory diseases, infarct, and trauma, and these etiologies must be considered and carefully excluded when evaluating these patients, with particular attention paid to the brainstem where several cranial nerves localize together (Fig. 89.1). However, occasionally, there may be abnormal findings limited to one cranial nerve in isolation. In these instances of isolated cranial neuropathies, the differential diagnosis depends on the nerve involved and the clinical picture as a whole. This chapter addresses common cranial mononeuropathies and their evaluation and management. Several of these are addressed in other chapters of this text and are referred to when appropriate. In particular, the cranial nerves II, III, IV, and VI are covered elsewhere covering visual disturbances (Chapter 10), eighth cranial nerve disorders are described in Chapter 62.

THE OLFACTORY NERVE (CRANIAL NERVE 1)

The ability to smell is a special quality relegated to the olfactory cells in the nasal mucosa. The molecular biology of smell is uncertain, but transcription-activating factors, such as Olf-1, found exclusively in neurons with olfactory receptors, probably direct cellular differentiation. Smell may be impaired after injury of the nasal mucosa, the olfactory bulb or its filaments, or CNS connections. Nerve injury causes diminution or loss of the sense of smell. The most common complaint of patients with olfactory nerve injury, however, is not loss of smell but diminished taste; olfaction plays a key role in taste perception because of the volatile substances in many food and beverages. A loss of sense of smell may be congenital or acquired and occurs in various conditions (Table 89.1). The sense of smell is most commonly impaired, transiently, because of allergic nasal congestion or the common cold. The most common traumatic olfactory nerve injury occurs in head injury, usually of the acceleration-deceleration variety, including motor vehicle accidents. The delicate olfactory nerve filaments are sheared by the perforations of the cribriform plate. The olfactory bulb can also be contused or lacerated in head injuries. Leigh and Zee (2006) reported altered olfactory sense in 7.2% of patients with head injuries at a military hospital, with complete loss in 4.1% and partial loss in 3.1%. Recovery of smell occurred in only 6 of 72 patients. In a study of head injuries in civilians, Friedman and Merritt (1944) found that the olfactory nerve was damaged in 11 (2.6%) of 430 patients. In all patients, anosmia was bilateral. In three, the loss was transient and disappeared within 2 weeks of injury. *Parosmia* (ie, perversion of sense of smell) was present in 12 patients.

FIGURE 89.1 Cranial nerve nuclei. (From Siegel A, Sapru HN. *Essential Neuroscience*. 3rd ed. Philadelphia, PA: Wolters Kluwer; 2015.)

TABLE 89.1 Causes of Loss of Smell Related to Olfactory Nerve Injury

Congenital	Refsum disease Kallmann syndrome Congenital anosmia
Acquired	Inflammatory • Rhinitis • Meningitis • Mononeuritis multiplex Head trauma Tumor • Meningioma at olfactory groove • Frontal lobe glioma • Metastasis Neurodegenerative • Parkinson disease • Alzheimer disease Toxic • Cocaine • Cadmium • Smoking • Chemotherapeutic agents Vitamin deficiency • Thiamine (B_1) • B_{12} Psychiatric disease

Inflammatory or neuritic lesions of the bulb or tract are uncommon, but these structures are sometimes affected in meningitis or in mononeuritis multiplex. Rarely, patients with diabetes mellitus have impaired smell, sometimes stemming from olfactory nerve infarction. Hyposmia or anosmia is also common early in Refsum disease (an autosomal recessive disease leading to an overaccumulation of phytanic acid). Kallmann syndrome is an X-linked inherited disorder causing hypogonadism and anosmia due to olfactory tract hypoplasia. The olfactory bulb or tract may be compressed by meningiomas (particularly at the olfactory groove or sphenoidal ridge), metastatic tumors, or aneurysms in the anterior fossa or by infiltrating tumors of the frontal lobe. The Foster-Kennedy syndrome is a classic syndrome caused by a tumor invading the orbitofrontal region, leading to unilateral and ipsilateral optic atrophy, contralateral papilledema, and anosmia. Neurodegenerative diseases at times may be heralded by a loss of smell, and this is seen particularly with Parkinson disease, where loss of smell may be a presenting sign. Certain drugs are often implicated in a loss of smell, particularly cocaine when used intranasally, although other toxins such as cadmium and chemotherapeutic agents have been implicated as well.

Parosmia is not accompanied by impairment of olfactory acuity and is most commonly caused by lesions of the temporal lobe, although it has been reported with injury to the olfactory bulb

or tract. Olfactory hallucinations may occur in psychosis or as a seizure aura that involves the hippocampal or uncinate gyrus; perceptions are described as strange, unpleasant, and ill-defined odors. Increased sensitivity to olfactory stimuli is generally rare, although it may occur in migraineurs and in patients with reactive airways disease, perhaps because of prior sensitization to olfactory triggers. Cases in which the sense of smell is so acute that it is a source of continuous discomfort, however, may be psychogenic.

THE TRIGEMINAL NERVE (CRANIAL NERVE V)

The fifth cranial nerve, or the trigeminal nerve, has both a large sensory component as well as a smaller motor component. The nerve has three major branches—the ophthalmic division (V1), the maxillary division (V2), and the mandibular division (V3). These three branches carry sensory information from distinct dermatomes of the face, head, and mucous membranes and converge on the trigeminal or gasserian ganglion located in Meckel cave (which serves as the dorsal root ganglion). Sensory fibers from all three divisions ascend in the pons to terminate in the three parts of the trigeminal nucleus. The spinal trigeminal nucleus receives afferent fibers related to facial pain and temperature sensation, the principal sensory nucleus receives fibers related to light touch and mechanoreception, whereas the mesencephalic nucleus contains cell bodies with fibers carrying information regarding jaw proprioception. Motor branches originate in the motor nucleus of the trigeminal nerve and are distributed in the mandibular division to innervate the muscles of mastication.

Injury to the fifth cranial nerve causes loss of soft tactile, thermal, and pain sensation in the face; loss of the corneal and sneezing (ie, sternutatory) reflexes; and paralysis of the muscles of mastication. Lesions of the trigeminal pathways in the pons usually affect the motor and chief sensory nuclei causing paralysis of the muscles of mastication and loss of light touch perception in the face; lesions in the medulla affect only the descending tract and cause loss of facial pain and temperature sensation. Brain magnetic resonance imaging (MRI) with contrast is often useful to search for mass lesions, ischemia, and inflammation, whereas electrophysiologic testing (eg, blink reflex testing) may help quantitate both the afferent (ie, trigeminal nerve) and efferent (ie, facial nerve) components of the corneal reflex. The fifth cranial nerve may be injured by trauma, neoplasm, aneurysm, or meningeal infection. Infarcts and other vascular lesions, as well as intramedullary tumors, may damage the sensory and motor nuclei in the pons and medulla. Isolated lesions of the descending tract may occur in syringobulbia or in multiple sclerosis. Common causes of trigeminal nerve injury with facial numbness include dental or cranial trauma, herpes zoster, head and neck tumors, intracranial tumors, and idiopathic trigeminal neuropathy. Less common causes include multiple sclerosis, systemic sclerosis, mixed connective tissue diseases, amyloidosis, and sarcoidosis. Isolated facial numbness may also occur without a clearly identifiable cause (ie, *idiopathic trigeminal neuropathy*), but these patients must be carefully evaluated to ensure an occult process is not overlooked. Although restricted loss of sensation over the chin (ie, the *numb chin syndrome*) usually is caused by dental trauma, dental or surgical procedures, or even poorly fitting dentures, this syndrome is a recognized initial feature of a systemic malignancy such as lymphoma, metastatic breast carcinoma, melanoma, or prostate cancer. MRI of the mandible may help separate these disorders. Painful facial numbness may herald nasopharyngeal or metastatic carcinoma. Isolated weakness of the trigeminal innervated muscles of mastication may be seen in motor neuron disease where patients often develop jaw weakness and dysphagia. This can also be seen with diseases of the neuromuscular junction, that is, myasthenia gravis.

Trigeminal Neuralgia

Epidemiology and Pathobiology

Trigeminal neuralgia, also commonly known as *tic douloureux*, is a syndrome of extremely severe facial pain without numbness or objective findings in the fifth cranial nerve distribution (see also Chapter 57). This disorder of the trigeminal nerve is characterized by recurrent paroxysms of sharp, stabbing pains in the distribution of one or more nerve branches. Unlike herpes zoster, the second and third divisions of the trigeminal nerve are the most commonly involved, and the first is primarily affected in only less than 5% of patients. Onset is usually in middle or late life but may occur at any age. Typical trigeminal neuralgia occasionally affects children but rarely occurs before age 35 years—presentation at that age should prompt an investigation for demyelinating disease. The incidence of trigeminal neuralgia is slightly greater in women than in men and found to be about 12.6 per 100,000 people in some studies.

The cause remains unknown. In most cases, no organic disease of the fifth cranial nerve or the CNS is identified. Degenerative or fibrotic changes in the gasserian ganglion have been described but are too variable to be considered causal. Trigeminal nerve compression related to an anomalous blood vessel, usually in the vicinity of the ganglion, is a long-standing but controversial etiology of the disorder. Most commonly, this is thought to be compression by a loop of either the anterior inferior cerebellar or superior cerebellar artery. Painful symptoms typical of trigeminal neuralgia occasionally occur with demyelinating brainstem lesions including those produced by multiple sclerosis as well as vascular ischemia affecting the descending root of the fifth cranial nerve. When trigeminal neuralgia has a known structural cause, it is categorized as symptomatic, as opposed to the idiopathic form that has no known etiology. Although trigeminal neuralgia usually follows other symptoms of multiple sclerosis rather than precedes them, up to 10% of patients may have facial pain as part of their initial presentation. Tumors invading the gasserian ganglion or the cerebellopontine angle may also cause symptoms of trigeminal neuralgia, although usually in the setting of an abnormal neurologic examination. The paroxysmal attacks of facial pain in trigeminal neuralgia may be related to excessive discharge within the descending nucleus of the nerve triggered by an influx of impulses. Relief of symptoms by section of the greater auricular or occipital nerves in some patients suggests a role for peripheral excitation and interruption of an episode by intravenous phenytoin, as well as a general therapeutic response to antiepileptic agents, suggests aberrant neuronal discharge may also play an important part in the pathophysiology of this disorder. Trigeminal neuralgia is the most common of all neuralgias.

Diagnosis

The pain is extremely severe and is described by many patients as among the worst pain imaginable, and in severe and refractory cases, the risk of suicide is increased. The pain appears in paroxysms and typically lasts seconds, although episodes of

up to 15 minutes can occur. Between episodes, the patient is free of symptoms, except for fear of an impending attack. The pain is searing or burning, coming in lightning-like jabs. The frequency of attacks varies from many times a day to a few times a month. The patient ceases to talk when the pain strikes and may rub or pinch the face; movements of the face and jaw may accompany the pain. Sometimes, ipsilateral lacrimation is prominent. No objective loss of cutaneous sensation is found during or after the paroxysms, but the patient may complain of facial hyperesthesia.

A characteristic feature in the presentation is the *trigger zone*, stimulation of which sets off a typical paroxysm of pain. This zone is a small area on the cheek, lip, or nose that may be stimulated by facial movement, chewing, brushing teeth, or touch. The patient may avoid making facial expressions during conversation, may go without eating for days, or may avoid the slightest breeze to prevent an attack. The pain is limited strictly to one or more branches of the fifth cranial nerve and does not spread beyond the distribution of that nerve. The second division is involved more frequently than the third. Pain may spread to one or both of the other divisions. In cases of long duration, all three divisions are affected in 15% of patients. The pain is occasionally bilateral (5%) for some but rarely occurs at the same time. Bilateral trigeminal neuralgia is encountered most often in patients with multiple sclerosis. A new classification scheme differentiates classic trigeminal neuralgia with paroxysms of pain from a different form, in which the paroxysms are associated with a concomitant dull, constant facial pain.

The diagnosis of trigeminal neuralgia is usually made from the history. Neurologic examination in patients with trigeminal neuralgia is usually normal, although some patients may also have concurrent hemifacial spasm, and patients whose attacks are provoked by eating may appear thin or cachectic. The results of serum studies and other diagnostic evaluations are also normal. Characteristically, patients avoid touching the area of origin when asked to point it out, instead holding the tip of the index finger a short distance from the face. On examination, patients will show no clinical sensory or motor deficits in the trigeminal nerve distribution, although the affected area is often very sensitive. Computed tomography or MRI of the brain is reasonable to exclude structural causes and, at times, may demonstrate an aberrant vessel causing compression. However, the sensitivity and specificity of MRI for identifying neurovascular compression is variable, and thus, its role for this purpose is controversial. In 2008, the American Academy of Neurology put forth a practice parameter concerning the diagnosis and treatment of trigeminal neuralgia, which stated that electrodiagnostic evaluation of the trigeminal reflex is a reasonable first step in excluding symptomatic trigeminal neuralgia and can be considered before imaging.

Trigeminal neuralgia must be differentiated from other types of facial pain or headache, especially infections of the teeth and nasal sinuses. These pains are usually steady instead of episodic, are often throbbing, and persist for many hours. However, it is not uncommon for patients with trigeminal neuralgia to undergo surgical treatment of the sinuses and/or tooth extractions before the diagnosis is established. Conversely, patients with diseased teeth may be referred to neurology with a diagnosis of trigeminal neuralgia, although careful dental examination usually identifies the teeth as the source of pain in these patients.

Temporomandibular joint disease may also mimic trigeminal neuralgia, but the pain is not paroxysmal and, although exacerbated by eating, no trigger point may be identified and symptoms are usually less severe between meals. Cluster headaches are another consideration but occur in protracted clusters rather than as brief events and are accompanied by ipsilateral nasal congestion, ipsilateral conjunctival injection and lacrimation, and an ipsilateral Horner syndrome. Atypical facial pain may have a trigeminal distribution, but the individual paroxysms always last longer than a few seconds (usually minutes or hours). The pain itself is dull, aching, crushing, or burning. Surgical treatment is not effective in atypical facial pain, and its etiology remains obscure, although it may be associated with depression.

A more detailed discussion of headache and facial pain syndromes can be found in Chapter 9.

Management and Outcome

Although surgical options now exist, medical therapy remains first line as far as treatment options. Trigeminal neuralgia is most effectively treated with carbamazepine at 800 mg/d to a maximum dose of 1,600 mg/d in four divided doses LEVEL 2.[1] A Cochrane Database review found carbamazepine to be consistently effective, with a number needed to treat of 1.8. However, dosing should be titrated to effect, and doses producing serum levels above the therapeutic range for seizure control may be needed as long as potentially dose-limiting side effects are tolerated. Overdosage is manifested by drowsiness, dizziness, ataxia, unsteady gait, and nausea. Hepatotoxicity may occur but is usually reversible with discontinuation. Another more rare but serious complication is aplastic anemia, and both periodic liver function testing and monitoring of the blood count are needed. In some patients, tolerance may develop over time. Baclofen is also effective in many cases in doses of 40 to 80 mg/d; phenytoin is less effective but may be used as adjunctive therapy. Some of the newer antiepileptic agents may also provide some relief, and oxcarbazepine, a derivative of carbamazepine, in doses of 600 to 1,800 mg/d is thought to be as effective as carbamazepine. Pimozide (a dopamine receptor antagonist) was found to be effective in a randomized, double-blind crossover trial to be effective at doses of 2 to 12 mg/d; however, its clinical use is limited given risk of serious side effects including arrhythmias and acute parkinsonism. Other medications which have been shown to be effective in some cases (although no controlled trials exist) include lamotrigine, gabapentin, pregabalin, levetiracetam, phenytoin, and topiramate. More recently, both intravenous lidocaine and onabotulinum toxin A have been found to be successful in treating acute episodes of trigeminal neuralgia, although more rigorous trials are needed. Topical ophthalmic anesthesia is probably ineffective for controlling pain. Surgical procedures used to treat this condition include microvascular decompression, radiofrequency ablation, balloon microcompression, and chemical gangliolysis and rhizotomy. More recently, stereotactic radiosurgery using Gamma Knife has been used with noted improvements in pain scores. Of these methods, radiofrequency ablation has met with the greatest success in initial treatment, although recurrence rates have not been studied carefully. As compression of the trigeminal nerve by arterial loops may play a role in some cases, posterior fossa exploration with decompression has sometimes been used for refractory cases. Other chronic masses, such as arteriovenous malformation, aneurysm, and cholesteatoma, may also cause compression of the ganglion and may be more amenable to surgical correction.

THE FACIAL NERVE (CRANIAL NERVE VII)

The seventh cranial nerve (facial nerve), although predominantly motor, also serves an important parasympathetic and sensory function (Fig. 89.2). On exiting the brainstem ventrally via the internal acoustic meatus in the petrous part of the temporal bone near the pontomedullary junction, the facial nerve forms two divisions: the nervus intermedius and the motor root. The motor root is composed of nerve fibers arising from the facial motor nucleus, and after exiting the nucleus, these axons travel dorsomedially in the pons to circle the abducens nucleus (thus forming the facial colliculus) and travel down to meet the nervus intermedius to form the facial nerve. The nervus intermedius arises from superior salivatory and lacrimal nuclei (eventually sending parasympathetic innervation to the salivary glands, specifically the submaxillary and sphenopalatine ganglia), the nucleus solitarius (fibers of which ultimately relays afferent taste sensation from the anterior two-thirds of the tongue), and the spinal trigeminal nucleus (carrying somatosensory afferent fibers to parts of the face and ear). The fibers of the seventh cranial nerve arising from the spinal trigeminal nucleus may also relay proprioceptive impulses from the facial muscles and cutaneous sensation from the posteromedial surface of the pinna and the external auditory canal. The fibers arising from the nucleus solitarius and spinal trigeminal nucleus together synapse in the geniculate ganglion in close proximity to the brainstem. Distal to the geniculate ganglion, the facial nerve forms several branches. Axons from the superior lacrimal nucleus form the greater petrosal nerve, which synapses in the sphenopalatine ganglion prior to innervating the lacrimal glands. Fibers originating from the nucleus solitarius and the superior salivatory and nuclei travel further distally in the facial nerve prior to forming the chorda tympani, a branch of the nerve which crosses the middle ear and exits the skull to join the lingual nerve. Just prior to the chorda tympani, the facial nerve also gives off a motor

FIGURE 89.2 Anatomy of the facial nerve. (From Campbell WW. *DeJong's The Neurologic Examination*. 6th ed. Philadelphia, PA: Lippincott Williams and Wilkins; 2005.)

branch to the stapedius muscle. Distal to the chorda tympani, the motor root of the facial nerve runs through the facial canal and exits the skull via the stylomastoid foramen. At this point, it gives rise to the posterior auricular nerve innervating the scalp and ear as well as a motor branch to the stylohyoid muscle and digastric muscle. The nerve then continues on into the parotid gland, where it divides into its five major branches—temporal, zygomatic, buccal, marginal mandibular, and cervical.

Lesions near the origin of the nerve, or in the vicinity of the geniculate ganglion, are accompanied by loss of motor, gustatory, and autonomic functions. Lesions between the geniculate ganglion and the origin of the chorda tympani typically spare lacrimation, whereas lesions near the stylomastoid foramen spare taste and lacrimation, causing only ipsilateral facial paralysis of the upper and lower face. Lesions of the facial nerve nucleus in the brainstem also cause ipsilateral paralysis of all facial muscles, both upper and lower.

The pattern of peripheral or nuclear injury (the peripheral seventh nerve lesion) must be distinguished from that associated with central motor pathway lesions above the level of the nucleus, which cause weakness and paralysis in the lower half of the face while sparing forehead wrinkling because of redundancy of central pathways subserving upper face muscles (central facial weakness; supranuclear palsy) (**Fig. 89.3**). In supranuclear lesions, voluntary contractions of the face differ, being more or less intense, from those occurring during spontaneous emotional expression, particularly when accompanied by laughing or crying. Depending on the precise site and extent of associated injury within the CNS, other neurologic signs may also appear.

Owing to this anatomic organization, the signs of peripheral facial nerve injury are somewhat variable (**Table 89.2**). More severe injury produces obvious facial paralysis at rest with sagging of the muscles of the lower ipsilateral face. The normal folds and lines around the lips, nose, and forehead are attenuated; the palpebral fissure is wider than normal; and voluntary movement of the facial and platysmal muscles is absent. Smiling highlights the weakness by contrasting the normal and unaffected orbicularis oris with the droop of the affected side. Although weakness of both the upper and lower halves of the face is seen, occasionally, the lower muscles may be weaker than the upper, or more rarely, the upper muscles may be weaker than the lower, with partial nerve injury. Saliva may seep from the paralyzed side of the mouth at rest, and food or fluids may leak out when eating. Closure of the eyelid is incomplete, and the upward and inward deviation of the eye may be seen during examination when eye closure is attempted (Bell phenomenon). This common complication assumes great importance because early patching and lubrication of the affected eye after seventh cranial nerve injury is critical to prevent corneal desiccation and potentially permanent scarring. Tear production is diminished only if the lesion is proximal to the geniculate ganglion. With lesions peripheral to the ganglion, lacrimation is spared, but tears may still be sequestered in the conjunctival sac because incomplete eyelid closure no longer moves them effectively through the lacrimal duct. The corneal reflex is also impaired by paralysis of the upper lid, although preservation of corneal sensation and the afferent portion of the reflex is confirmed by consensual blinking of the contralateral eyelid during corneal reflex testing. Decreased salivation and loss of taste in the anterior two-thirds of the tongue are present when the chorda tympani is affected. Loss of somatic sensation to the external auditory canal, however, is less common. The seventh nerve also supplies the stapedius muscle, and patients may develop increased sensitivity to loud sounds (ie, hyperacusis) when the small muscle is paralyzed, and its dampening effect on the tympanic membrane is lost. Recovery from facial paralysis depends on the severity of the lesion and the specific cause. If the nerve is completely crushed or severed, the chances of even partial recovery are remote, especially if the intraneural scaffolding necessary to guide axonal regeneration is lost. In contrast, in purely demyelinative lesions without axonal injury, excellent and often complete recovery is expected. When the facial nerve attempts to regenerate through proximal axonal growth across an injured segment, axonal extension sometimes results in aberrant reinnervation. This faulty circuit results in the movement of previously unrelated facial muscles when the patient attempts isolated activation of a separate muscle, a process known as *synkinesis*. In such patients, for example, lip movement may occur with each eye blink. Aberrant reinnervation may also cause excessive lacrimation during activation of the facial muscles or when the salivary glands are activated during eating (eg, producing "crocodile tears"). In addition, some patients develop paroxysmal clonic contractions of the hemifacial muscles (ie, hemifacial spasm) that may simulate focal seizures.

Bell's Palsy

Epidemiology and Pathobiology

Bell's palsy, named after the Scottish anatomist Charles Bell, is a common clinical syndrome of uncertain etiology in which acute, unilateral paresis or paralysis of muscles innervated by the facial nerve appears spontaneously, over hours to days, and is the most common cause of facial nerve injury and acute mononeuropathy. It occurs at all ages but is slightly more common in the third to fifth decades and is equally likely to affect the right or left sides. Bell's palsy is the common cause of facial nerve paralysis and in one study accounted for 65% of cases of peripheral facial paralysis in a pediatric population (excluding congenital causes). Recurrence, either on the same or on the opposite side, is rare and raises the question of a more generalized disorder. Familial Bell's palsy is reported but is also rare. Risk factors are not well defined, although some patients report exposure of the affected side to a steady breeze or fan for several hours just prior to onset. It has also found to be associated with diabetes mellitus, pregnancy, and hypertension. Some postulate that it may be caused by reactivation of a latent herpes simplex virus or varicella-zoster and possibly human herpesvirus 6. Lyme disease is also often implicated particularly in cases of bilateral facial palsy.

Diagnosis

Pain is not typical except in the Ramsay Hunt syndrome (see the following section), which is caused by herpes zoster and is usually accompanied by vesicular eruption in the sensory distribution of the seventh cranial nerve in the ipsilateral ear. Patients typically present with unilateral facial weakness or complete paralysis, which can be scored from 1 to 6 on the House-Brackmann scale, which is determined by measurements of eyebrow and mouth movements. Depending on the location of the lesion, facial weakness may be associated with diminished lacrimation and/or impaired taste in the anterior two-thirds of the tongue on the affected side, and a weakened or absent blink reflex is always present. Given the innervation of the stapedius muscle, there may be an increased sensitivity to noise on the affected side. There should not, however, be any impairment of eye movements, change in vision, or other bulbar symptoms such as dysphagia or facial numbness. When present, any of those signs

FIGURE 89.3 Central versus peripheral seventh nerve palsy. (From Dugani S, Alonsi JE, Agur AMR, Dalley AF. *Clinical Anatomy Cases*. Philadelphia, PA: Wolters Kluwer; 2017.)

TABLE 89.2 Clinical Manifestations of Lesions of the Facial Nerve

Location of Lesion	Motor Function	Gustatory Sensation	Lacrimation
At facial nerve nucleus in pons	Impaired	Impaired	Impaired
Origin of nerve/geniculate ganglion	Impaired	Impaired	Impaired
Between geniculate ganglion and chorda tympani	Impaired	Impaired	Spared
At stylomastoid foramen	Impaired	Spared	Spared

or symptoms should prompt one to look for an alternative diagnosis. In 2013, the American Academy of Otolaryngology—Head and Neck Surgery Foundation published a new clinical practice guideline on the diagnosis and treatment of Bell's palsy. Regarding appropriate diagnostic workup, it was concluded that in the appropriate clinical scenario following a complete history and examination, there is no role for laboratory investigation, diagnostic imaging, or electrodiagnostic testing (unless there is complete facial paralysis). Patients should, however, be referred to a specialist in cases of new or worsening findings, ocular symptoms, or incomplete recovery 3 months after onset. Nevertheless, nerve conduction studies of the extracranial portion of the facial nerve are at times performed (particularly in cases of complete

paralysis) along with needle recordings from its myotomes (eg, facial muscle electromyography) to help determine the nature and degree of injury. Injury to the intracranial portion may be detected by blink reflex testing.

Treatment and Outcome

Although permanent deficits may occur in severe cases, the vast majority of patients with Bell's palsy experience full, functional recovery with minimal to no residual signs. Long-term prognosis is typically very favorable, although there is some recent limited evidence that these patients may be at a slightly higher risk for developing cancer (particularly oral cancer) and a slightly higher risk of stroke. Inflammation, herpes simplex virus infection, and swelling with compression may be involved in the pathogenesis of Bell's palsy, so steroids, antiviral medication (acyclovir), and surgical decompression have been advocated as acute therapy. A large, randomized controlled study showed that 94% receiving prednisolone 25 mg twice a day for 10 days had a good recovery at 9 months compared with 82% who did not receive steroids LEVEL 2.[2,3] The same study showed no benefit for the antiviral agent acyclovir at doses of 400 mg five times per day for 10 days, although another large study showed benefit for valacyclovir at 1 g/d for 5 days. Surgical intervention has been looked at as well, and a recent Cochrane Database review found insufficient evidence to decide whether it is beneficial or harmful, but given the generally good prognosis and spontaneous recovery is often not recommended. Early physical therapy may be beneficial particularly in cases of very severe paresis or complete paralysis. The 2013 American Academy of Otolaryngology—Head and Neck Surgery Foundation practice guidelines recommend offering antiviral therapy in addition to oral steroids with 72 hours of symptom onset, although made no recommendation regarding the use of physical therapy, acupuncture, or surgical referral. The American Academy of Neurology published an update regarding recommendations on steroids and antiviral therapy which stated that steroids should be offered to those with new-onset palsy and that antiviral may be offered although are likely to be of modest benefit at best. It is important that affected patients patch the weak eye overnight because weakness of eye closure may lead to dry eyes and corneal abrasions. Eye drops such as artificial tears and lubricating ointments should be given as well. The prognosis of facial nerve injury after Bell's palsy has also been the focus of much discussion. In general, preservation of motor amplitudes on nerve conduction studies after 7 to 10 days supports retained axonal integrity and suggests a favorable prognosis for recovery. In contrast, rapid loss of motor amplitudes suggests prominent axonal involvement, wallerian degeneration, and poorer chance for functional improvement. Needle electromyography examination may also aid in detecting denervation change, further supporting axonal injury. Electroneurography has recently been looked at with regard to its prognostic value, and electroneurography value was found to be positively correlated with a higher chance of recovery in both Bell's palsy and Ramsay Hunt syndrome, although it is not commonly used in practice. In the long term, patients may develop synkinesis as described earlier. In patients with incomplete or poor recovery, facial reanimation surgery may be offered.

Ramsay Hunt Syndrome

Ramsay Hunt syndrome, also known as *herpes zoster oticus*, is another cause of facial mononeuropathy, although much less common than Bell's palsy and tends to affect younger patients. Mean incidence is thought to be about five cases per 100,000 person-years. It is caused by a reactivation of a latent varicella-zoster virus infection affecting the geniculate ganglion leading to inflammation of the facial nerve and therefore is seen commonly in immunocompromised conditions (ie, posttransplant, in the setting of malignancy). Typically, in addition to facial weakness, as in Bell's palsy, there is associated hyperacusis, diminished taste, and impaired salivation and lacrimation. The degree of weakness in these patients is often more severe than in those with Bell's palsy, and pain is a distinguishing factor. Pain is very common and can be in deep to the face; in the ear; or in the orbit, tongue, or palate (particularly if sensory fibers are involved). Most commonly, there is pain behind the ear on the affected side. On examination, one may see herpetic vesicles in the external auditory canal or behind the ear and at times may also be found on the neck and palate (Fig. 89.4). However, a rash is not always seen (or may erupt after the onset of weakness), and one must have a high index of clinical suspicion based on the patient's history and presentation in order to consider this diagnosis rather than Bell's palsy. Herpetic infection can spread to the eighth cranial nerve leading to complaints of nausea, tinnitus, and vertigo and infrequently to other cranial nerves as well.

Both steroids and antivirals have been used to treat Ramsay Hunt syndrome with varying degrees of success. Although there have been no randomized controlled trials, several studies have noted that early administration of steroids and antivirals (within 3-5 d) leads to improved facial and vestibulocochlear nerve recovery. Some suggest using intravenous methylprednisolone in those patients not improving or with poor prognostic factors. Overall, patients with Ramsay Hunt syndrome have an overall poorer prognosis than those with Bell's palsy and often have an incomplete recovery.

Other Causes of Facial Nerve Injury

Many other processes may significantly damage the facial nerve. Intracranially, it may be injured by tumors, aneurysms, meningeal infections, leukemia, osteomyelitis, herpes zoster, Paget disease, sarcomas, and bony tumors, among others. It may also be damaged by leprous polyneuritis, Guillain-Barré syndrome, and diphtheritic polyneuropathy. Diabetic seven cranial nerve mononeuropathies may also occur but are less common than other cranial mononeuropathies in that disorder. The peripheral segment of the nerve may be compressed by tumors of the parotid gland, sarcoidosis, and, more rarely, mumps. Bilateral facial palsy also may be caused by many of the same conditions producing unilateral paralysis but is most often seen in sarcoidosis, Guillain-Barré syndrome, leprosy, leukemia, and meningococcal meningitis. Sarcoid, in fact, can be implicated in most cranial neuropathies and a full discussion of neurosarcoidosis can be found in Chapter 75. *Melkersson-Rosenthal syndrome* is a syndrome presenting in childhood characterized by a constellation of clinical symptoms and signs including facial and lip edema, a furrowed and fissured tongue (lingua plicata), and recurrent attacks of facial weakness. Although there is no known etiology, it is thought to be familial in some instances. Other congenital causes of facial palsy include Möbius syndrome, in which facial weakness is associated with impaired lateral eye movement due to poor development of both the seventh and sixth cranial nerves. The facial nucleus, itself, may be damaged by vascular lesions, multiple sclerosis, intraparenchymal tumors, inflammatory lesions, and acute poliomyelitis, among others. The relatively superficial peripheral branches of the seventh cranial nerve are vulnerable to stab and gunshot wounds, cuts, and in neonates, birth trauma. Occasionally, the nerve is also injured in surgeries involving the mastoid and parotid glands, acoustic neuroma resection, and trigeminal ganglion decompression as well as in fractures of the temporal bone.

Cases of facial nerve injury with a specific, identifiable cause may require aggressive intervention. Microsurgical anastomosis may be performed in some cases of transection of the extracranial nerve or its branches. However, when the nerve is damaged proximal to the stylomastoid foramen, operative anastomosis becomes more difficult. Surgery may still be indicated, however, if a mass lesion is found before excessive damage is done. In cases of partial or inaccessible intracranial facial nerve injury, compensatory surgical reinnervation may be provided by suturing the distal portion of the 7th cranial nerve to the central portion of either the 11th or the 12th cranial nerve. With rehabilitative training, these patients may learn to reroute impulses formerly destined for the sternocleidomastoid (SCM) muscle, or half of the tongue, to the newly rewired facial musculature. However, use of the 11th cranial nerve for this procedure causes permanent paralysis of the SCM and upper fibers of the trapezius muscle, whereas use of the 12th cranial nerve causes atrophy and paralysis of one-half of the tongue. Anastomosis of the facial nerve with either the 11th or the 12th cranial nerve should be performed as soon as possible following acute injury, such as with surgical misadventure by surgery of the mastoid or removal of an acoustic neuroma, for instance. In other situations, surgery may need to be delayed for up to 6 months or more to determine whether spontaneous regeneration occurs.

Hemifacial spasm is a disorder involving involuntary muscle contractions of facial muscles on one side of the face and is covered in detail in Chapter 80.

THE GLOSSOPHARYNGEAL NERVE (CRANIAL NERVE IX)

The 9th cranial nerve contains both motor and sensory (general as well as taste) fibers. The motor fibers originating in the nucleus ambiguus supply the stylopharyngeus muscle and the constrictors of the pharynx, whereas other efferent fibers innervate secretory glands in the pharyngeal mucosa. The sensory fibers carry general sensation from the upper part of the pharynx (as well as the tonsil, tympanic membrane, and external ear) and the special sensation of taste from the posterior one-third of the tongue. The glossopharyngeal nerve also conveys sensory afferent fibers from the carotid sinus and body by way of the nucleus solitarius and provides parasympathetic innervation to the parotid gland via the otic ganglion through the lesser petrosal nerve. Isolated lesions of the nerve, or its nuclei, are rare and are not accompanied by perceptible disability. Taste is lost on the posterior one-third of the tongue, and the gag reflex is absent on the side of the lesion. Injuries of the 9th cranial nerve by infections or tumors are rarely isolated and are usually accompanied by signs of injury to nearby cranial nerves. As the 9th, 10th, and 11th cranial nerves exit the jugular foramen together, tumors at that point produce multiple cranial nerve palsies (ie, *jugular foramen syndrome*). Within the brainstem, the tractus solitarius receives taste fibers from both the 7th and the 9th cranial nerves and is commonly injured by vascular or neoplastic lesions in the brainstem.

Glossopharyngeal Neuralgia

Glossopharyngeal neuralgia (GN), also known as *tic douloureux* of the ninth cranial nerve, is characterized by paroxysms of excruciating pain in the region of the tonsils, posterior pharynx, and back of the tongue with radiation to the middle ear. The cause of GN is unknown, and no significant pathologic changes occur in most cases. Idiopathic GN must be differentiated from pain in the distribution of the nerve following its injury in the neck by tumors. GN is rare, with a frequency of approximately 5% that of trigeminal neuralgia. Unlike trigeminal neuralgia, men and women are affected equally, and GN is more likely to be bilateral than trigeminal neuralgia. The paroxysms consist of burning or stabbing pain and may occur spontaneously but are often precipitated by swallowing, talking, or touching the tonsils or posterior pharynx. The attacks usually last only a few seconds but sometimes may last several minutes, and they may occur many times daily or once every few weeks. Patients may become emaciated because of the fear that chewing each morsel of food will precipitate a pain paroxysm; general quality of life may be seriously affected, especially in severe cases. On occasion, attacks may lead to syncope, arrhythmia, or convulsions due to stimulation of the carotid sinus reflex.

The diagnosis of GN is best made by history and may be confirmed by provocative testing (eg, precipitation by stimulation of the tonsils, posterior pharynx, or base of the tongue) or by transient relief of pain following the application of topical anesthetic to the ninth cranial nerve dermatome. Following this procedure, the pain is no longer precipitated by stimulation, and the patient may swallow food and talk without discomfort until the anesthetic wears off. The differential diagnosis is limited but includes neuralgia of the mandibular branch of the fifth cranial nerve. There may be long remissions, during which pain is no longer triggered. The pains usually recur, however, unless

prevented by medical therapy or surgical resection of the nerve. Medications used to treat trigeminal neuralgia are equally effective with GN, and carbamazepine alone or in combination with phenytoin often provides effective control and induces a pharmacologic remission. Duloxetine as well as certain newer antiepileptic drugs such as pregabalin, gabapentin, topiramate, and lamotrigine might also be effective.

If medical therapy is unsuccessful and the pain is intractable, surgical interventions have been shown to be effective, including microvascular decompression, radiofrequency ablation, and Gamma Knife ablation. Intracranial transection of the nerve may also provide relief. Following this procedure, the mucous membrane supplied by the 9th cranial nerve is permanently anesthetized, with ipsilateral loss of the gag reflex and ipsilateral loss of taste on the posterior one-third of the tongue. Motor symptoms, such as dysphagia or dysarthria, are not typical unless the 10th cranial nerve is injured during surgery.

THE VAGUS NERVE (CRANIAL NERVE X)

Efferent fibers of the vagus nerve arise from both the nucleus ambiguus and the dorsal motor nucleus. Fibers from the nucleus ambiguus ultimately innervate the somatic muscles of the pharynx and larynx through the pharyngeal, superior laryngeal, and recurrent laryngeal nerves, whereas those from the dorsal motor nucleus supply autonomic innervation to the heart, lungs, esophagus, and stomach. The vagus nerve also relays sensory fibers from the mucosa in the oropharynx and upper part of the gastrointestinal tract to the spinal nucleus of the trigeminal nucleus and relays sensory fibers from the thoracic and abdominal organs to the tractus solitarius. Central lesions of the above nuclei in the brainstem cause a number of symptoms. Unilateral lesions of the nucleus ambiguus result in dysarthria and dysphagia, although rarely is the condition severe. However, because the nucleus has a considerable longitudinal extent in the medulla, such lesions may produce dysarthria without dysphagia or vice versa (ie, caudal nuclear lesions cause dysphagia, whereas rostral lesions produce dysarthria). Hoarseness may also occur, but speech is usually intelligible. Dysphagia is usually slight, although occasionally, a more severe transient aphagia necessitates the use of a feeding tube for days to weeks. On examination, contraction of the palatal muscles is absent on the affected side during gag reflex testing. The palate on the affected side is lax at rest, and the uvula deviates to the opposite side on phonation, drawn away from the paralyzed muscles by normal, contralateral, palatal contraction (ie, contralateral uvular deviation).

In contrast to the mild deficits typically seen with unilateral lesions, bilateral lesions of the nucleus ambiguus cause complete aphonia and aphagia. Focused bilateral injury of this type is rare but may be seen in advanced amyotrophic lateral sclerosis (ALS) in the setting of pseudobulbar palsy. Selective destruction of portions of the nucleus ambiguus may be produced by syringobulbia, intramedullary tumors, or ischemia and may cause a clinical syndrome of vocal cord paralysis during adduction. The patient may talk and swallow without difficulty, but inspiratory stridor and dyspnea may appear and progress sufficiently to require tracheotomy. Unilateral lesions of the dorsal motor nucleus are not accompanied by any significant symptoms, but bilateral lesions may produce life-threatening autonomic instability. The dorsal nucleus may be damaged by infection (eg, acute poliomyelitis), intramedullary tumor, ischemia, and polyneuropathy, especially that associated with diphtheria and Guillain-Barré syndrome.

Individual branches of the vagus nerve are most amenable to injury in the neck, thorax, and, less commonly, the abdomen. Injury to the pharyngeal branches of the vagus nerve causes dysphagia, whereas lesions of the superior laryngeal nerve produce anesthesia of the upper part of the larynx and paralysis of the cricothyroid muscle. In these cases, the voice is weak and easily fatigable. Injury to a single, recurrent laryngeal nerve (ie, frequently seen with aneurysms of the aorta, tumors or trauma of the neck, and occasionally after operations in the neck) causes unilateral paralysis of the vocal cords with hoarseness and dysphonia; bilateral injury causes complete vocal cord paralysis with aphonia and inspiratory stridor. Partial bilateral paralysis may produce a paralysis of both abductors, with severe dyspnea and inspiratory stridor, but does not usually cause any alteration in the voice. Bilateral lesions of the vagus nerve invariably lead to death via cardiac arrhythmias, irregular respirations, gastrointestinal atonia, and complete paralysis of the pharynx and larynx.

THE SPINAL ACCESSORY NERVE (CRANIAL NERVE XI)

The spinal accessory nerve is composed of two primary branches—the first is a small accessory cranial branch contributing visceral efferent fibers to the vagus nerve, which emerges from the jugular foramen to blend with the vagus as it descends (primarily in the recurrent laryngeal nerve). The majority of the accessory nerve, the spinal portion, innervates the SCM and part or all of the trapezius muscles. Its fibers originate in the upper cervical spinal cord (C2, C3, and C4), enter the skull via the foramen magnum, and travel through the jugular foramen along the carotid artery to innervate the SCM muscle. Another branch emerges in the mid-SCM at its posterior border and crosses the posterior triangle of the neck to innervate the upper trapezius. It is important to note that supranuclear efferents to the SCM are primarily ipsilateral, whereas inputs to the trapezius cross contralaterally from the motor cortex. Therefore, on examination, a lesion of the ipsilateral hemisphere or accessory spinal nerve will result in an inability to turn the head contralaterally (as the SCM turns the head in the opposite direction). Fibers of the spinal accessory nerve also travel in the medial longitudinal fasciculus, where they make connections with the oculomotor, trochlear, abducens, and vestibular nuclei and help coordinate eye movements with head motion in response to external stimuli.

Lesions of the spinal portion of the 11th cranial nerve produce weakness and atrophy of the trapezius muscle and SCM, impairing rotary movements of the neck and chin to the opposite side, and weakness of shrugging movements of the shoulder. Weakness of the upper portion of the trapezius results in winging of the scapula, which must be differentiated from that produced by weakness of the serratus anterior. Scapular winging from weakness of the trapezius is present at rest (eg, arms at side) and becomes worse on abduction of the shoulder. Scapular winging from weakness of the serratus anterior is negligible at rest and worsens during flexion of the shoulder (holding or pushing the arm forward). Bilateral paralysis of the trapezius may present with "dropped head syndrome" due to weakness of head extension. With unilateral SCM weakness, there is typically little head tilt, as there are contributions

from several other muscles to head rotation, although the patient will have difficulty turning the head to the contralateral side. The accessory or cranial portion of the nerve originates in the nucleus ambiguus and passes through the jugular foramen with the 10th cranial nerve, traveling with the spinal fibers (see earlier), eventually innervating the larynx, and functionally is considered by some to be a part of the vagus nerve complex.

The nucleus of the 11th cranial nerve may be destroyed by infections and degenerative disorders in the medulla, such as syringobulbia or ALS. The nerve itself may be injured by polyneuropathy, meningeal infection, extramedullary tumor (eg, meningioma and neurinoma), trauma (ie, basilar skull fracture), or by destructive processes in the occipital bone. It is particularly vulnerable to damage along its course in the posterior triangle of the neck, for instance, during lymph node biopsy, radiation, cannulation of the internal jugular vein, or carotid endarterectomy. The SCM and trapezius are also often involved in cases of extrapyramidal dysfunction (discussed in later chapters), such as torticollis due to cervical dystonia. Idiopathic focal mononeuropathies of the spinal accessory nerve exists although are rare, and the nerve at times may be involved in cases of Parsonage-Turner syndrome. Primary diseases of muscle and the neuromuscular junction also commonly involve the muscles innervated by the 11th cranial nerve, such as in fascioscapulohumeral dystrophy, myotonic dystrophy, and myasthenia gravis. Diagnosis of a spinal accessory nerve palsy is made clinically but can be supported with imaging and electrodiagnostic testing. Recent reports point to a potential role for ultrasound in diagnosis and in determining etiology.

FIGURE 89.5 Tongue weakness. (From Bhatnagar SC. *Neuroscience for the Study of Communicative Disorders*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2013.)

THE HYPOGLOSSAL NERVE (CRANIAL NERVE XII)

The hypoglossal nerve (a pure motor nerve) emerges from the medulla between the ventrolateral sulcus, between the olive and the pyramids, as a number of rootlets that converge into the hypoglossal nerve. The nerve then exits the cranium through the hypoglossal foramen in the posterior cranial fossa traveling close to cranial nerves IX, X, and XI and passing downward near the inferior ganglion of the vagus to lie between the internal carotid artery and internal jugular vein. It then crosses laterally to the bifurcation of the common carotid artery and loops above the hyoid bone before moving ventrally to supply the genioglossus (which has crossed supranuclear innervation) and other muscles of the tongue with the exception of the palatoglossus (innervated by the vagus nerve). The 12th cranial nerve and its nucleus may be injured by most of the same processes that damage the 10th and 11th nuclei. Occlusions of the short branches of the basilar artery supplying the paramedian medulla cause paralysis of the tongue on one side and paralysis of the arm and leg on the opposite side (ie, alternating hemiplegia). Unilateral injury to the nucleus results in atrophy and paralysis of the muscles of one-half of the tongue causing deviation toward the paralyzed side with protrusion (Fig. 89.5).

Fibrillation of the muscles is seen with chronic injury to the hypoglossal nerve or its nucleus in syringobulbia or ALS and may be observed as miniscule twitching of the surface of the tongue on visual inspection. Bilateral paralysis of the nucleus or nerve produces atrophy of both sides of the tongue and paralysis of all movements with severe dysarthria and difficulty manipulating food in the mouth. The tongue is only rarely affected by supranuclear lesions within the CNS; unilateral weakness may accompany severe hemiplegia with slight deviation of the tongue to the paralyzed side when protruded. Moderate weakness of the tongue may accompany pseudobulbar palsy but is never as severe as that caused by destruction of both medullary nuclei. The hypoglossal nerve is susceptible to injury anywhere along its course (both intra and extramedullary) and can be involved in cases of meningitis, neoplastic infiltration, trauma, lymphadenopathy, radiation, and processes involving the skull base. Occasionally, muscle diseases may involve the tongue, such as in myotonic dystrophy where percussion of the tongue may cause a temporary contraction along the line of percussion.

90 Mononeuropathies and Compression Neuropathies

Thomas H. Brannagan III

KEY POINTS

1. Carpal tunnel syndrome is one of the most common mononeuropathies, caused by compression of the median nerve at the wrist.
2. The brachial plexus is composed of the upper, middle, and lower trunks and medial, posterior, and lateral cords.
3. Electromyography showing myokymia is frequently seen in plexus lesions caused by radiation.

APPROACH TO PERIPHERAL NERVE DISORDERS

Mononeuropathy indicates a disorder of a single nerve often resulting from local trauma, compression, or entrapment. *Mononeuropathy multiplex* signifies focal involvement of two or more nerves, usually as a result of a generalized disorder such as diabetes mellitus or vasculitis. This chapter discusses an approach to mononeuropathies, including plexus disorders.

Epidemiology

Mononeuropathies are common disorders. One mononeuropathy, carpal tunnel syndrome, is estimated to occur in 3% to 5.8% and is 3 times more common in women than men. People in occupations, doing tasks, requiring high force and repetition, such as food processing, carpentry, and roofing are at higher risk.

Clinical Features

In *mononeuropathy* or *mononeuropathy multiplex*, focal motor, sensory, and reflex changes are restricted to areas innervated by specific nerves. When multiple distal nerves are affected in mononeuropathy multiplex, the pattern may coalesce into more symmetric involvement suggesting polyneuropathy. Mononeuropathy multiplex is discussed in Chapter 91.

Processes that affect nerve roots are termed *radiculopathies* and affect a single or multiple myotomes or dermatomes. Focal compression is most common, but other processes also target nerves at these proximal sites. Electric-like pain radiating down a specific segment is most characteristic; loss of sensation or strength in a specific territory occurs with more severe involvement. *Plexopathy* occurs with compromise of the brachial or lumbosacral plexus and often displays a pattern of multiple contiguous nerves or nerve root impairment.

Etiology and Diagnosis

Trauma, compression, and entrapment are considered in the differential diagnosis of mononeuropathies, especially median neuropathy at the wrist, ulnar nerve at the elbow, or fibular nerve across the fibular head. Patients with any form of polyneuropathy are more vulnerable to mechanical and toxic nerve injury; cachectic or immobile patients may develop focal neuropathy from pressure or trauma.

Outcome

With mononeuropathies, the prognosis is affected by the extent of nerve degeneration. With removal or treatment of the inciting cause, recovery is more rapid if macroscopic continuity of the nerves is maintained. Conversely, recovery may be delayed for many months or remain incomplete if significant wallerian degeneration occurs. Axonal regeneration proceeds at a rate of 1 to 2 mm/d and may be further delayed where the axons must penetrate scar tissue, injured nerve segments, or other barriers. Aberrant growth of axonal sprouts may lead to formation of persistent neuromas. After severe wallerian degeneration, there may be permanent weakness, muscular wasting, diminution of reflexes, and sensory loss.

THE SPINAL ROOTS AND BRACHIAL PLEXUS

At each cervical spinal level, numerous rootlets containing both motor and sensory fibers join after leaving the spinal cord to form the spinal roots that exit the spinal canal through the intervertebral foramen of the spinal column, immediately branching into anterior and posterior rami. The nerve roots are commonly injured by degenerative joint disease and disk herniation at the cervical and lumbosacral levels. Importantly, the dorsal root ganglia (ie, the cell bodies of the sensory nerves) are located outside the foramen and are spared in foraminal compression, meaning the remainder of the sensory nerve will remain viable and will appear normal on nerve conduction studies, even though it is disconnected from the central nervous system and the patient reports numbness and pain. Before forming the brachial plexus, the C5 nerve root gives off a proximal branch, the *dorsal scapular nerve* (to the rhomboid muscles), whereas the C5, C6, and C7 roots give proximal branches that join to form the *long thoracic nerve*, supplying the serratus anterior muscle. The C5 and C6 roots then join to form the *upper trunk* of the brachial plexus, whereas the C7 root forms the *middle trunk*, and the C8 and T1 roots form the *lower trunk*. The upper trunk gives off a small branch, the *suprascapular* nerve, which supplies the supra- and infraspinatus muscles. All trunks pass through the supraclavicular fossa under the cervical and scalene muscles.

FIGURE 90.1 The brachial plexus. (From Haymaker W, Woodhall B. *Peripheral Nerve Injuries*. Philadelphia, PA: WB Saunders; 1945.)

Each trunk then forms two branches, and these branches regroup to form new divisions, the cords, as they course through the *thoracic outlet*, between the first rib and the clavicle, along with the subclavian artery. The lateral branches of the upper and middle trunks contribute to the *lateral cord* (ie, C5, C6, C7), whereas the medial branches join with the lateral branch of the lower trunk and move dorsally to form the *posterior cord* (ie, C5, C6, C7, C8). Finally, the lower trunk gives rise to the *medial cord* (ie, C8, T1). The *lateral and medial pectoral nerves* branch off near the juncture of the trunks and the lateral and medial cords, respectively, supplying the pectoralis major muscle.

The *thoracodorsal nerve* that supplies the latissimus dorsi and the *subscapular* nerve that supplies the teres major each branch medially off the posterior cord. The posterior cord persists distally, becoming the *radial nerve*, after giving off a smaller lateral branch, the *axillary nerve*, which supplies the deltoid. The lateral and medial cords then each contribute a branch to form the *median nerve*, composed of the medial branch of the lateral cord and the lateral branch of the medial cord, joined in the middle of the plexus. The lateral branch of the lateral cord persists distally, becoming the *musculocutaneous nerve*, whereas the medial branch of the medial cord becomes the *ulnar nerve* (**Fig. 90.1**; **Tables 90.1** and **90.2**).

The brachial plexus may be injured by traumatic, neoplastic, infectious, radiation, and other processes. Careful history and neurologic examination, in concert with a detailed understanding of plexus anatomy, is the first step in recognizing plexus injury and differentiating it from injury to the nerve roots or peripheral nerves. Electrophysiologic assessment with electromyography (EMG) and nerve conductions is often critical in confirming the diagnosis, and imaging studies may also be indicated. Mixed syndromes of radicular plexus and peripheral nerve injury may also occur, making localization even more challenging. The roots or trunks of the brachial plexus may be damaged by lacerations, gunshot wounds, or direct trauma. They may be compressed by tumors or aneurysms or stretched and torn by violent movements of the shoulder in falls, dislocation of the shoulder, carrying heavy loads on or over the shoulder, and by traction during birth. The syndromes of the roots and trunks cause deficits principally in the distribution of the affected nerve roots. Partial paralysis and incomplete sensory loss are common because many muscles of the arm receive innervation from two or more roots.

TABLE 90.1 Innervation of the Muscles of the Shoulder Girdle

Muscle	Nerve	Spinal Nerve Roots
Sternocleidomastoid	Accessory	X1, C2, C3
Trapezius	Accessory	C3, C4
Serratus anterior	Long thoracic	C5, C7
Levator scapulae	Dorsal scapular	C5, C6
Rhomboideus major	Dorsal scapular	C5, C6
Rhomboideus minor	Dorsal scapular	C5, C6
Subclavius	Subclavian	C5, C6
Supraspinatus	Suprascapular	C5, C6
Infraspinatus	Suprascapular	C5, C6
Pectoralis major	Medial and lateral pectoralis	C5, C6
Pectoralis minor	Medial pectoralis	C5, C6
Teres major	Subscapular	C5, C6
Latissimus dorsi	Thoracodorsal	C6, C7
Subscapularis	Subscapular	C5, C6
Deltoid	Axillaris	C5, C6
Teres minor	Axillaris	C5, C6

TABLE 90.2 Innervation of Muscles of the Arm and Forearm

Muscle	Nerve	Root
Biceps brachii *Brachialis*	Musculocutaneous	C5, C6
Triceps	Radialis	C7, C8
Anconeus	Radialis	C7, C8
Brachioradialis	Radialis	C5, C6
Extensor carpi radialis	Radialis	C6, C7
Pronator teres	Medianus	C6, C7
Flexor carpi radialis	Medianus	C7, C8
Palmaris longus	Medianus	C7, C8
Flexor digitorum sublimis	Medianus	C7, C8
Flexor digitorum profundus	Medianus, ulnaris	C7, C8
Flexor carpi ulnaris	Ulnaris	C7, C8
Supinator	Radialis	C7, C8
Extensor digitorum communis	Radialis	C7, C8
Extensor digiti minimi	Radialis	C7, C8
Extensor carpi ulnaris	Radialis	C7, C8
Abductor pollicis longus and brevis	Radialis	C7, C8
Extensor indicis proprius	Radialis	C7, C8

Trunk and Root Injury

Upper Radicular Syndrome

Upper radicular syndrome (Erb or Erb-Duchenne palsy) results from damage to the upper roots (C4, C5, or C6) or the upper trunk. Such lesions are most commonly the result of stretch injuries during difficult deliveries, especially when forceps are used, and cause paralysis of the deltoid, biceps, brachioradialis, pectoralis major, supraspinatus, infraspinatus, subscapularis, and teres major muscles in varying combinations. If the lesion is near the roots, the serratus anterior, rhomboids, and levator scapulae are also paralyzed. Clinically, this causes weakness of flexion at the elbow and of abduction and internal and external rotation of the arm. There is also weakness or paralysis of apposition of the scapula and backward-inward movements of the arm. Sensory loss is incomplete and consists of hypesthesia on the outer surface of the arm and forearm. The biceps reflex is absent. Unless treated by passive range-of-motion exercise, these patients may develop chronic contractures with the arm extended at the side, fully adducted, and pronated, with the hand flexed and facing rearward (eg, the waiter's tip position).

Middle Radicular Syndrome

Middle radicular syndrome results from damage to the seventh cervical root (C7) or the middle trunk. Such lesions cause paralysis primarily of the muscles supplied by the radial nerve except the brachioradialis, which is entirely spared. Clinical weakness parallels that of injury to the radial nerve below the level of its branch to the brachioradialis. Sensory loss is variable and, when present, is limited to hypesthesia over the dorsal surface of the forearm and the external part of the dorsal surface of the hand.

Lower Radicular Syndrome (Klumpke Palsy)

Lower radicular syndrome (Klumpke palsy) results from injury to the lower trunk or lower roots (C7-T1), which causes paralysis of the flexor carpi ulnaris, the flexor digitorum, the interossei, and the thenar and hypothenar muscles. This pattern mimics a combined lesion of the median and ulnar nerves. Clinically, a flattened or simian hand is seen, with loss of all intrinsic hand musculature and with loss of sensation on the inner side of the arm and forearm and on the ulnar side of the hand. The triceps reflex is lost. If the communicating branch to the inferior cervical ganglion is injured, there is paralysis of the sympathetic nerves, causing a Horner syndrome.

Cord Injury

Lesions of the cords cause motor and sensory loss resembling that seen after injury to two or more peripheral nerves. *Lateral cord* injury causes weakness in the distribution of the musculocutaneous nerve and the lateral head of the median nerve, including weakness in the pronator teres, flexor carpi radialis, and flexor pollicis. *Posterior cord* injury causes weakness paralleling that resulting from combined damage to the radial and axillary nerves, whereas *medial cord* injury mimics combined damage to the ulnar nerve and the medial head of the median nerve (finger-flexion weakness).

Diffuse Plexus Injury

Generalized injury to the brachial plexus is usually unilateral but occasionally appears bilaterally. Such injury results from a more diffuse polyneuropathy, such as chronic inflammatory demyelinating neuropathy, or from multifocal motor neuropathy. A variety of insults may produce injury selectively affecting the brachial plexus, but tumor infiltration, radiation plexitis, and idiopathic plexitis are among the most important. Almost any neoplasm with a propensity for the chest may affect the plexus, but those cancers originating locally, such as lung and breast cancer, are most likely to cause injury. Such tumors may cause extrinsic compression of the plexus as they grow or may directly infiltrate the nervous tissue. Other neoplasms, such as lymphoma, may infiltrate the plexus and cause progressive deficits without any apparent mass effect or enlargement of the plexus itself in the initial stages. Magnetic resonance imaging (MRI) with contrast is the best way to confirm these lesions.

Idiopathic brachial plexitis (also known as the *Parsonage-Turner syndrome* or *neuralgic amyotrophy*) usually begins with a sudden, sharp pain affecting one shoulder, often with radiation down the ipsilateral arm, later followed by arm or shoulder weakness. The pain persists for hours or a few days with gradual improvement and usually resolves completely within days to weeks, leaving some sensory and motor dysfunction. It may be bilateral or asymmetric. Localization is often difficult because plexus involvement ranges from diffuse to multifocal and often includes patchy injury to the nerve branches off the plexus (eg, the axillary nerve).

Electrodiagnostic studies, if performed at least 14 to 21 days after onset, usually localize the injury to the plexus but may demonstrate multifocal involvement. Patterns of both axonal and demyelination injury have been reported. The diversity of physiologic disorders in different nerves or even within the same nerve is attributed to involvement of the terminal nerve twigs or to patchy damage of discrete bundles of fibers within the cords or trunks of the brachial plexus or its branches. The long thoracic and anterior interosseous nerves are commonly affected. Autoimmune or infectious causes have been suggested, but the etiology is obscure. Some cases have occurred in small epidemics, and the disorder may follow intravenous heroin use, human immunodeficiency virus seroconversion, surgery, and delivery.

There is no clear evidence that immunosuppressive therapy alters the course of the disease. However, short courses of tapering oral steroids are often prescribed if the patient presents shortly after symptom onset. Variants of this syndrome have also been described, including one with isolated, pure sensory injury affecting the lateral, antebrachial, cutaneous, and the median nerves.

A hereditary form that is frequently recurrent and bilateral is rarely encountered. Lumbosacral plexitis also occurs but much less frequently. Recovery depends on the severity of the initial insult. Although most patients recover well over 6 to 12 months, some are left with permanent disability. It is considered good in about 66%, fair in 20%, and poor in 14%. Clinical recovery may take 2 months to 3 years.

Thoracic Outlet Syndrome

The term *thoracic outlet syndrome* (TOS) encompasses different syndromes that arise from compression of the nerves in the brachial plexus or blood vessels (ie, subclavian or axillary arteries, or veins in the same area). The putative compression sources are also diverse. How often these lesions are actually responsible for symptoms and how the symptoms should be treated are matters of intense debate. Studies done mainly by orthopedists, vascular surgeons, and neurosurgeons have included reports on several hundred patients who were treated surgically for this syndrome. When neurologists write about the neurogenic form of TOS, however, the tone is always skeptical, and the syndrome is described as exceedingly rare, with an annual incidence of about 1 per 1 million persons.

Pathology

The T1 and C8 nerve roots and the lower trunk of the brachial plexus are exposed to compression and angulation by anatomic anomalies that include cervical ribs and fibrous bands of uncertain origin. Other nearby structures, such as scalene muscles, are dubious sources of compression. Cervical ribs are commonly found in asymptomatic people, and it is therefore difficult to assume that the presence of a cervical rib necessarily explains local symptoms. In addition to the neural syndromes, the same anomalies may compress local blood vessels and cause vascular syndromes, usually separated into arterial and venous entities. These conditions are also rare and may cause neurogenic symptoms by distal nerve ischemia but not pressure on the brachial plexus. Some cases follow local trauma.

Clinical Features

Patients have pain in the shoulders, arms, and hands, or sometimes in all three locations. Hand pain is often most severe in the fourth and fifth fingers. The pain is aggravated by use of the arm, and arm "fatigue" may be prominent, meaning local discomfort after brief effort. There may or may not be hypesthesia in the affected area.

Critics have divided cases into two groups: the *true* neurogenic TOS and the *disputed* syndrome. In the *true* syndrome, there are definite clinical and electrodiagnostic abnormalities. This disorder is rare and is almost always caused by a taut fibrous band extending from a cervical rib or abnormally elongated C7 transverse process; the band stretches the distal C8 and T1 roots or lower brachial plexus trunk. There is unequivocal wasting and weakness of hand muscles innervated by these segments. Changes are almost always unilateral.

Electromyography and nerve conduction studies demonstrate a pattern of low-amplitude median motor, ulnar sensory, and medial antebrachial cutaneous-evoked responses. Ulnar motor responses to hypothenar muscles may be involved to a lesser degree. EMG signs of active and chronic denervation are limited to involved muscles, most severely in the abductor pollicis brevis, and are attributed to a major contribution from T1.

In the *disputed* form, there are no objective motor or sensory signs or consistent laboratory abnormalities. Attempts to reproduce the syndrome by passive abduction of the arm (ie, the Adson test) or other maneuvers have been cited, but the same abnormalities may be found in normal people and have no specific diagnostic value. The diagnosis is usually made by the treating surgeon; symptoms are frequently bilateral and complicated by legal or other nonmedical issues.

Similarly, studies of the application of electrodiagnostic techniques have not been blinded or controlled, so less specific abnormalities have been noted; the findings include isolated abnormalities of ulnar sensory nerve amplitude, conduction velocity after stimulation of the Erb point, ulnar F waves, and ulnar somatosensory-evoked potentials. MRI may show deviation or distortion of nerves or blood vessels, bands extending from the C7 transverse process, or other local anomalies. MRI quantitative estimates of the size of the thoracic outlet may show smaller than average dimensions, as were the cases in blinded reviews of series that compared vascular and neurogenic patients together with controls but do not prove that the differences are causative. Magnetic resonance angiography and Doppler ultrasonography may help assess possible vascular compression.

Diagnosis and Treatment

In cases of *true* TOS, diagnosis must exclude entrapment syndromes in the arm and compressive lesions in the cervical spine. The "upper limb tension test" is said to be comparable to straight leg raising, is carried out by abducting the arms to 90° in external rotation, bringing on symptoms within 60 seconds. EMG, MRI, and sonography after raising the arm have been used to aid in diagnosis. However, warnings continue to appear about false-positive maneuvers to evoke pain. Danielson and Oddersen injected botulinum toxin into the anterior scalene muscle under ultrasound guidance. Subclavian artery flow rates were measured with Doppler ultrasound. Three weeks later, symptoms had improved and blood flow in the artery, tested with the arm extended, had improved. A placebo-controlled formal study of this "scalene muscle chemodenervation" would help resolve the uncertainty of the procedure, which could be used for diagnosis, treatment, and screening for surgery. However, no consensus has been achieved for the surgical procedure of choice, which may or may not include botulinum, rib resection, brachial plexus neurolysis, scalenectomy, or release of the subclavian artery and vein. Exercise programs have also been advocated.

In the *disputed* form, when no objective findings are noted on neurologic examination, there are problems. Each case must be evaluated separately, but caution is reasonable when symptoms are not accompanied by objective changes. Conservative therapy should be given an adequate trial; postural adjustments, passive exercise to increase mobility of shoulder muscles, and an exercise program have all been advocated. The results of surgery are difficult to evaluate without objective signs or diagnostic laboratory abnormalities to track; placebo effects are rarely considered in the evaluation of surgery. Symptomatic improvement also appears to be unrelated to the surgical procedure or the particular structure that has been excised or resected. Surgery is not without hazard; complications may include causalgia, injury of the long thoracic nerve, infection, and laceration of the subclavian artery.

THE SPINAL ROOTS AND LUMBAR AND SACRAL PLEXUSES

The Lumbar Plexus

The spinal roots at L2, L3, and L4 join to form the *lumbar plexus* in the psoas major muscle. This plexus gives off a number of principally sensory nerves, including the iliohypogastric, the ilioinguinal, the genitofemoral, and the lateral femoral cutaneous. The *femoral nerve* is derived from the L2, L3, and L4 roots, passing to the anterior leg along the lateral aspect of the psoas muscle (which it supplies); exiting the pelvis; and passing under the inguinal ligament to supply the pectineus, sartorius, rectus femoris, vastus lateralis, vastus intermedius, and vastus medialis muscles; and terminates as the pure sensory saphenous nerve in the medial lower leg.

The *obturator nerve* arises from anterior branches of the L2, L3, and L4 roots, forming in the psoas muscle and entering the pelvis anteriorly to the sacroiliac joint. It passes through the obturator canal, branching anteriorly to supply the adductor longus and brevis, and the gracilis, as well as posteriorly to supply the obturator externus, and half of the adductor magnus. It carries sensation from a small and variable area on the inner surface of the medial thigh, knee, and occasionally just below the medial knee.

The Sacral Plexus

The sacral plexus is formed from the L5, S1, and S2 roots, with variable contributions from L4. The *superior gluteal nerve* arises from the L4, L5, and S1 roots and supplies the gluteus medius and minimus and tensor fascia lata; the *inferior gluteal nerve* arises from the L5 and S1 roots and supplies the gluteus maximus.

The *sciatic nerve* is formed from the posterior fusion of the L4, L5, and S1 roots, exiting the pelvis via the greater sciatic foramen and passes through or under the piriformis muscle. It is functionally divided into a lateral fibular portion, which supplies the short head of the biceps femoris, and a medial tibial portion, which supplies the long head of the biceps femoris, the semitendinosus, and the semimembranosus. The nerve divides into the common fibular (formerly called the *peroneal*) and tibial nerves above the posterior knee.

The *common fibular nerve* branches laterally from the sciatic trunk in the popliteal fossa then moves superficially to wind around the head of the fibula. It then divides into the *superficial fibular nerve* to supply the peroneus longus and peroneus brevis and the *deep fibular nerve*, which supplies the tibialis anterior, extensor hallucis longus, peroneus tertius, and extensor digitorum brevis. The *tibial nerve* supplies the gastrocnemius and soleus, tibialis posterior, flexor digitorum longus, and flexor hallucis longus. It descends through the lower leg between the medial malleolus and the flexor retinaculum, dividing into the *medial plantar nerve* to supply the abductor hallucis, flexor digitorum brevis and flexor hallucis brevis, and the *lateral plantar nerve* to supply the abductor digiti minimi, flexor digiti minimi, abductor hallucis, and interosseous muscles. Both the tibial and fibular nerves supply sensory branches, which join to form the *sural nerve* below the popliteal space.

Radiation Plexopathy

Irradiation for carcinoma may damage nervous tissue, especially with high-voltage therapy. Brachial plexopathy is seen after radiotherapy for breast cancer; caudal roots and lumbosacral plexus are sometimes affected by radiation therapy for testicular cancer or Hodgkin disease. The first symptom is usually severe pain, followed by paresthesia and sensory loss. There may be a latent period of 12 to 20 months; in milder cases, several years may elapse before symptoms appear. Limb weakness peaks many months later. Latency intervals of up to 20 years have been reported. The damage may affect a single peripheral nerve initially and then progress slowly to involve others. Clinically, tendon reflexes disappear before weakness and atrophy becomes obvious; fasciculation and myokymia may be prominent. EMG and conduction studies reveal evidence of axonal damage; myokymic discharges are characteristic and can help differentiate plexopathy caused by radiation from plexopathy caused by tumor infiltration. High-resolution MRI is also potentially useful. No effective treatment is known. Radiation-induced fibrosis and microvascular injury are suspected mechanisms.

THE PROXIMAL NERVES OF THE ARM

The Axillary Nerve

The axillary nerve is the last branch of the posterior cord of the brachial plexus before forming the radial nerve. It arises from C5 and C6, supplies the deltoid and teres minor muscles, and transmits cutaneous sensation from a small patch on the lateral shoulder. Axillary neuropathy may be caused by trauma, fracture, humeral head dislocation, and brachial plexitis. Weakness of arm abduction after the first 15° to 30° of movement is typical. Outward, backward, and forward movements of the arm are also weakened, although less dramatically. Sensory loss is limited to a small patch over the lateral deltoid.

The Long Thoracic Nerve

The long thoracic nerve arises from C5, C6, and C7 and supplies the serratus anterior muscle. This nerve is most commonly injured in isolation by forceful, downward pressure on the shoulder, which stretches and compresses it. Typically, such pressure is caused by carrying excessively heavy loads on the shoulder (eg, furniture, carpets, heavy sacks, backpacks slung over one shoulder), although it may also appear after acute impact, such as that occurring while playing football. A more archaic term, although one still in use, is *hod carrier's palsy*, in reference to the hod or container bricklayers formerly placed on the shoulder to carry bricks up to roof tops when constructing chimneys. Injury of this nerve destabilizes the scapula, causing winging, and prevents the rotation of the scapula needed to enable the last few degrees of abduction of the arm from 90° to 180° over the head. Injury following acute or chronic trauma is characterized by weakness in elevation of the arm above the horizontal plane. Winging of the scapula is most prominent when the arm is fully abducted or elevated anteriorly (Fig. 90.2). Winging is often not readily apparent with the arm resting at the side.

The Brachial Cutaneous and Antebrachial Cutaneous Nerves

The brachial and antebrachial cutaneous nerves branch directly from the C8 to T1 plexus and provide sensation to the medial arm and upper two-thirds of the forearm. These nerves are usually injured in conjunction with the medial cord of the brachial plexus and are rarely injured in isolation.

FIGURE 90.2 Paralysis of the serratus anterior muscle with winging of the scapula.

The Suprascapular Nerve

The suprascapular nerve fibers arise from C5 and C6, ultimately branching from the upper trunk of the brachial plexus. This primarily motor nerve innervates the supraspinatus and infraspinatus muscles. Affected patients have difficulty moving the arm from the side through the first 15° to 30° of abduction and with external shoulder rotation. Shoulder trauma or more diffuse brachial plexus injury is most common; isolated nerve injury is rare.

THE PERIPHERAL NERVES

The Radial Nerve

The radial nerve is a continuation of the posterior cord and contains elements of the C5, C6, C7, C8, and T1 nerve roots. It is predominantly a motor nerve and innervates the chief extensors of the forearm, wrist, and fingers. It descends through the axilla to supply the triceps, giving off three minor sensory branches to the upper arm and then winds posteriorly around the humerus in the *spiral groove*. After exiting the spiral groove, the nerve innervates the brachioradialis and extensor carpi radialis longus muscles then moves laterally to enter the forearm between the brachialis and brachioradialis muscles. There, it branches into a primary sensory component, the *superficial radial nerve*, which supplies sensation to the dorsoradial aspect of the distal forearm and the dorsal surface of the hand, and a motor component, the *posterior interosseous nerve*, which supplies all the remaining forearm extensor muscles and often the supinator as well (Table 90.3).

The clinical findings after radial nerve injury depend on the level of the lesion. Injury in the axilla, classically caused by improperly fitting crutches that are too long, causes triceps weakness as well as weakness of the remaining radial myotome and numbness in the radial dermatome. Injury in the spiral groove caused by humeral fracture or extrinsic compression (eg, *Saturday night palsy*) causes weakness of the radial myotome below the elbow, with prominent wrist-drop, weakness of finger extension, and sensory loss in the distribution of the superficial radial nerve but preserved elbow extension. Mild elbow flexor weakness may be present as a result of involvement of the brachioradialis, which should be easy to distinguish on physical examination. The posterior interosseous branch may also be injured by entrapment as it passes through the supinator muscle in the tight space of the arcade of Frohse.

Injury of the posterior interosseous nerve spares the brachioradialis and the extensor carpi radialis longus, as well as the superficial radial nerve, causing radial deviation of the wrist with attempted wrist extension but no sensory loss (ie, posterior interosseous neuropathy). Damage to the superficial radial branch may occur at the wrist as a result of tight-fitting jewelry or handcuffs, causing pure sensory loss over the dorsum of the hand without weakness. Evaluation of radial nerve injury often includes electrodiagnostic studies and may include imaging studies, depending on the site of the lesion. Treatment focuses on relieving the cause of compressive injury, if possible. Posterior interosseous nerve syndrome is sometimes treated with surgical release.

The Median Nerve

The median nerve derives from the C6 to T1 nerve roots, passing through the lateral and medial cords of the brachial plexus, which each contributes a segment to the nerve. The median nerve passes down the arm and through the two heads of the pronator teres at the level of the forearm, ultimately supplying the pronator teres as well as the flexor carpi radialis, palmaris longus, and flexor digitorum superficialis muscles. It then branches into the pure motor *anterior interosseous nerve*, which supplies the flexor pollicis longus, pronator quadratus, and flexor digitorum profundus I and II, and into a main branch, which passes through the carpal tunnel, further branching into the *recurrent thenar nerve*, supplying the abductor and the lateral flexor pollicis brevis and the opponens pollicis before terminating in the palm, where it supplies lumbricals I and II. Pronation is mediated by the pronator quadratus and pronator teres, wrist flexion by the flexor carpi radialis and palmaris longus, flexion of the thumb and the index and middle fingers by the superficial and deep flexors, and opposition of the thumb by the opponens pollicis (Table 90.4).

The median nerve supplies sensation to the radial side of the palm, the ventral thumb, index and middle fingers, the radial half of the ring finger, as well as the dorsal surfaces of the distal phalanx of the thumb, and the middle and terminal phalanges of the index and middle fingers. Isolated lesions of the median nerve cause weakness and sensory loss in the aforementioned distributions, but only a few movements are paralyzed because of the synergistic contributions of muscles innervated by other nerves to these movements. However, there may be absence of flexion in the index finger and near-complete paralysis of the opponens pollicis. The median nerve may be injured by trauma, ischemia, and other processes but most commonly is damaged by anatomic compression. It may be entrapped between the heads of the pronator teres muscle, causing weakness and sensory loss in the above distributions, with sparing of the pronator teres itself, which is innervated more proximally (ie, the pronator teres syndrome).

Entrapment of the anterior interosseous nerve (ie, the anterior interosseous neuropathy) often presents with pain but produces no sensory loss. Symptoms include weakness of the flexor pollicis longus, flexor digitorum profundus I and II, and the

TABLE 90.3 Muscles Innervated by the Radial Nerve

Flexor pollicis longus	

pronator quadratus. Attempts to make the "OK" sign with the thumb and index finger produces a triangle rather than a circle (eg, the pinch sign). The most common of all the nerve entrapment syndromes is the *carpal tunnel syndrome*. This syndrome results from entrapment of the median nerve as it passes through the tunnel defined by the carpal bones and the transverse carpal ligament, resulting in pain and sensory loss in a distal median distribution; wasting and weakness of thenar muscles and median innervated lumbricals is seen in severe cases. Although the diagnosis is primarily clinical, electrophysiologic studies may confirm the lesion and provide information on severity. Conservative treatment with application of a neutral position wrist splint is often effective. More severe or refractory cases, especially when motor deficits appear or splinting or other conservative measures fail to provide relief, may be treated by surgical release of the carpal tunnel. Many underlying disorders may predispose to the condition including diabetes, uremia, hypothyroidism, amyloidosis, and pregnancy.

The Ulnar Nerve

The ulnar nerve arises from C8 to T1 roots and the medial cord of the brachial plexus. It passes between the biceps and triceps, moving posteriorly to pass behind the medial epicondyle in the ulnar groove. It enters the forearm through the cubital tunnel, supplying the flexor carpi ulnaris and the flexor digitorum profundus II and IV, then moves medially to enter the hand through Guyon canal, where it divides into a superficial sensory branch and a deep motor branch, which supplies the abductor, opponens, and flexor digiti minimi medially. It then moves laterally to the adductor pollicis and the medial half of the flexor pollicis brevis (Table 90.5).

The nerve supplies sensation to the palmar and dorsal surfaces of the little finger, the medial half of the ring finger, and both the palmar and dorsal sides of the ulnar portion of the hand. Complete lesions of the proximal ulnar nerve are characterized by weakness of flexion and adduction of the wrist and of flexion of the ring and the little fingers, paralysis of abduction and opposition of the little finger, paralysis of adduction of the thumb, and paralysis of adduction and abduction of the fingers, along with atrophy of the hypothenar muscles and the interossei. Atrophy of the first dorsal interosseous is especially obvious on the dorsum of the hand between the thumb and the index finger. Sensory loss is greatest in the little finger and is present to a lesser extent on the inner side of the ring finger. Chronic lesions result in clawing of ulnar innervated fingers. The ulnar nerve may be injured by trauma, ischemia, and other causes but similar to the median nerve, it is most commonly injured by compression. Entrapment primarily occurs in three locations. The most common site is at the elbow, in or just proximal to the ulnar groove. Just distal to the elbow, the nerve may become entrapped in the cubital tunnel, the tunnel formed by the aponeurosis connecting the two heads of the flexor carpi ulnaris. Proximal nerve injury causes weakness in the ulnar myotomes of the hand and may include the flexor carpi ulnaris and flexor digitorum profundus III and IV, depending on the precise site of the compression. The nerve is potentially compressed at the elbow by direct pressure from arms of chairs, table edges, and excessive elbow flexion. A protective elbow pad is useful in some cases. Various forms of surgical decompression are available for the most extreme cases. Guyon canal stenosis in the wrist, most commonly associated with a ganglion cyst, causes weakness and atrophy of intrinsic hand muscles. Sensory symptoms may be minimal, although nerve conduction studies to the digits are abnormal. However, the flexor carpi ulnaris and flexor digitorum profundus III and IV are spared, in addition to sensation on the dorsal hand surface, which is innervated by the dorsal ulnar cutaneous nerve that arises in the distal forearm. The innervation of hand muscles is summarized in Table 90.2.

TABLE 90.5 Muscles Innervated by the Ulnar Nerve

Flexor carpi ulnaris	Flexor digiti minimi
Flexor digitorum profundus (digits four and five)	All interossei
Palmaris brevis	Lumbricales (digits three and four)
Abductor digiti minimi	Flexor pollicis brevis
Opponens digiti minimi	

The Musculocutaneous Nerve

The musculocutaneous nerve originates from the C5 and C6 nerve roots and the main branch of the upper trunk of the brachial plexus. It provides innervation to the coracobrachialis, biceps brachii, and brachialis muscles and provides sensation to the ventrolateral forearm (lateral antebrachial sensory nerve) as well as to a small area on the dorsolateral outer surface of the forearm. Isolated injuries of the nerve are rare and it is not typically prone to focal compression. Lesions of the musculocutaneous nerve produce weakness of flexion and supination of the forearm, sensory loss in the musculocutaneous myotomes, and loss of the biceps reflex. Forearm flexion may still be performed by the brachioradialis muscle innervated by the radial nerve. However, because the bicep is the chief supinator of the forearm, this movement is paralyzed. Excessive windsurfing is associated with compression of the lateral antebrachial sensory branch.

THE NERVES OF THE LEG

The Obturator Nerve

Lesions of the obturator nerve are uncommon and may be caused by pelvic tumors, obturator hernias, and by passage of the head of the fetus during difficult labor. Injuries to the obturator nerve result in severe weakness of adduction and to a lesser extent, internal and external rotation of the thigh. Pain in the knee joint is sometimes caused by pelvic involvement of the geniculate branch of the obturator.

The Iliohypogastric Nerve

The iliohypogastric nerve is a predominately sensory nerve that originates from the uppermost part of the lumbar plexus. It provides sensation to the outer and upper parts of the buttocks and the lower part of the abdomen and supplies partial innervation to the internal oblique and transversalis muscles. Lesions of the iliohypogastric nerve are rare. It may be divided by incisions in kidney operations or together with the ilioinguinal nerve in operations in the inguinal region, such as hernia repair. Lesions of these nerves produce no significant motor loss and only a small area of cutaneous anesthesia.

The Ilioinguinal Nerve

The ilioinguinal nerve is also a branch of the upper lumbar plexus. It provides sensation to the upper inner portion of the thigh, the pubic region, and the external genitalia and supplies the transversalis, internal oblique, and external oblique muscles. The ilicinguinal nerve is usually injured in concert with the iliohypogastric nerve and is only rarely injured in isolation.

The Genitofemoral Nerve

This predominately sensory nerve originates from the second lumbar root and provides sensation to the scrotum and the contiguous area of the inner surface of the thigh. Lesions of the genitofemoral nerve are rare. Irritative lesions of the nerve in the abdominal wall are accompanied by painful hyperesthesia at the root of the thigh and the scrotum.

The Lateral Femoral Cutaneous Nerve of the Thigh

This nerve is formed by fibers from the second and third lumbar roots. It crosses beneath the fascia iliaca to emerge at the anterosuperior iliac spine, descends in the thigh beneath the fascia lata, and divides into two branches. The posterior branch passes obliquely backward through the fascia lata and provides sensation to the superior external buttock. The anterior branch, which is more important clinically, pierces the fascia lata through a small fibrous canal located about 10 cm below the ligament and provides sensation to the outer surface of the thigh.

Lesions to this nerve principally affect the anterior branch, causing the clinical syndrome of *meralgia paresthetica*, and includes dysesthesias and sensory loss along the lateral thigh. The use of tight, heavy, utility belts or corsets and religious talismans; obesity; weight loss; and pregnancy are implicated as possible contributors to compression. Pains in the lateral thigh may also be caused by spinal lesions or pelvic tumors, which must be excluded by appropriate diagnostic studies. The course of meralgia paresthetica is variable. Occasionally, symptoms disappear spontaneously. In most patients, removal of contributing factors aids in resolution of symptoms.

The Femoral Nerve

The femoral nerve may be compressed by tumors, other pelvic lesions, pubic ramus, or femur fractures, as well as by ischemia in diabetic neuropathy and other conditions. Assessment of hip adduction helps to separate this condition from lumbar plexopathy or radiculopathy.

Injury to the nerve produces weakness of leg extension and thigh flexion. Walking on level ground is possible so long as the leg is extended, but if the slightest flexion occurs, the patient's knee may collapse. Climbing stairs or walking uphill is difficult or impossible. The quadriceps reflex is lost on the affected side. Saphenous sensory loss is also diagnostically useful. In severe cases, orthopedic appliances that fix the knee joint in extension or tendon transposition may be considered.

The Sciatic Nerve

The main trunk of the sciatic nerve is derived from the lower lumbosacral nerve roots and retains a strict segregation of fibular and tibial fibers. Total paralysis of muscles innervated by the sciatic nerve is rare. Even with a lesion in the thigh, the common fibular division is often more severely damaged than the tibial.

Important sources of injury include gunshot, shrapnel, or stab wounds to the leg or pelvis; fractures of the pelvis or femur; dislocations of the hip; pressure of the fetal head during delivery; or pelvic tumors. The nerve is sometimes inadvertently injured by intramuscular injection of drugs, especially in infants. Compression can occur in the posterior thigh by sharp chair edges or operating room tables. Injury by the piriformis muscle (*piriformis syndrome*) is controversial but very rare, but convincing cases are described. *Sciatica* is a term used to describe pain in the low back and in the leg along the course of the nerve, but the vast majority of these patients have nerve root injury at the L5-S1 level, often caused by intervertebral disk herniation. The clinical features of cervical and lumbar disk herniation are considered in Chapters 113 and 114.

Complete injury of the sciatic nerve causes paralysis of all the movements of the ankle and toes as well as weakness or paralysis of knee flexion. Gait is marked by foot drop and the ankle jerk is lost, along with sensation on the outer surface of the leg, on the instep and sole of the foot, and over the toes.

The Common Fibular Nerve

The common fibular branch of the sciatic nerve is a mixed nerve innervating the extensor muscles of the ankle and toes and the foot evertors. It provides sensation from the outer side of the leg, the front of its lower one-third, the instep, and the dorsal surface of the four inner toes over their proximal phalanges. The common fibular nerve is highly subjected to trauma. It may be damaged by wounds near the knee. The nerve is readily compressed or stretched as it curves around the fibular head by leg crossing, squatting, or resting the edge of the leg against a hard surface while sleeping, intoxicated, or anesthetized. Ganglion cysts, sometimes palpable at the fibular head, are well described. Common fibular neuropathy results in foot drop and weak foot eversion. The patient may not dorsiflex the ankle, straighten or extend the toes, or evert the foot, and there is sensory loss in the nerve distribution. Recovery is dependent on the extent of injury, which usually correlates with the degree and duration of extrinsic compression. Ambulation in patients with footdrop may be greatly aided by ankle-foot orthoses.

The Tibial Nerve

Tibial neuropathy is uncommon. It may be injured by gunshot wounds or leg fractures. A complete lesion of the nerve produces paralysis of plantarflexion and inversion of the foot, flexion and separation of the toes, and sensory loss in the nerve distribution. The ankle jerk and plantar reflex are lost. Rarely, compression of the posterior tibial branch of the nerve at the medial malleolus produces pain and paresthesia in the soles of the feet in a manner similar to compression of the median nerve at the wrist (*tarsal tunnel syndrome*); however, this process is much less prevalent. Other conditions that produce foot pain and/or numbness, including digital neuropathy, focal disorders of the foot, plantar fasciitis, early polyneuropathy, and Morton neuroma that produce foot pain and numbness are all more frequent.

MONONEUROPATHIES IN DIABETES MELLITUS

It is generally believed but incompletely proven that focal neuropathies are more frequent in diabetic patients than in the general population. The syndromes are usually localized to common sites of nerve entrapment or external compression and may imply an increased liability to pressure palsies. This applies to the median nerve at the carpal tunnel, the ulnar at the elbow, and the fibular at the fibular head. The electrophysiologic features are similar to those seen in nondiabetic patients with pressure palsies, except that abnormalities outside the clinically affected areas sometimes indicate that the palsies are superimposed on a generalized neuropathy. Cranial nerve palsies are most often localized to the third and sixth nerves. They start abruptly and usually spontaneously resolve completely within 6 months; relapses are rare.

Acquired Peripheral Neuropathies 91

Thomas H. Brannagan III and Kurenai Tanji

KEY POINTS

1. Characterizing a polyneuropathy as multifocal demyelinating, uniform demyelinating, multifocal axonal, or generalized axonal may help narrow the differential diagnosis of the cause of a polyneuropathy.
2. Diabetes mellitus is now the most common cause of polyneuropathy worldwide.
3. Patients with distal polyneuropathies should be assessed for diabetes, a monoclonal protein, and vitamin B_{12}.
4. Even after a thorough evaluation, approximately 20% of all polyneuropathies and 50% of small-fiber polyneuropathy is idiopathic.
5. There is level 1 evidence for efficacy for intravenous immunoglobulin for Guillain-Barré syndrome, chronic inflammatory demyelinating polyneuropathy, and multifocal motor neuropathy.
6. There is level 1 evidence for efficacy for transthyretin stabilizers, such as diflunisal and tafamidis and RNA silencers, such as patisiran and inotersen for polyneuropathy associated with hereditary transthyretin amyloidosis.

APPROACH TO PERIPHERAL NERVE DISORDERS

The peripheral nervous system is composed of multiple cell types and elements that subserve diverse motor, sensory, and autonomic functions. The clinical manifestations of neuropathies depend on the severity, distribution, and functions affected. *Peripheral neuropathy* and *polyneuropathy* are terms that describe syndromes resulting from diffuse lesions of peripheral nerves, usually manifested by weakness, sensory loss, pain, and autonomic dysfunction. *Mononeuropathy* indicates a disorder of a single nerve often resulting from local trauma, compression, or entrapment. *Mononeuropathy multiplex* signifies focal involvement of two or more nerves, usually as a result of a generalized disorder such as diabetes mellitus or vasculitis. This chapter discusses an approach to peripheral nerve disorders and specific acquired polyneuropathies. Inherited neuropathies are discussed in Chapter 92, and mononeuropathies, including plexus disorders, are discussed in Chapter 90.

Epidemiology

Peripheral neuropathies of various causes are common disorders. A prevalence of 2% to 7% of symmetric polyneuropathy has been found in studies conducted around the world. Currently, the most common cause of peripheral neuropathy worldwide is diabetes, although prior to 1994, the most common cause of peripheral neuropathy worldwide was leprosy. The prevalence of peripheral neuropathy increases with age, affecting 15% of the population older than the age of 40 years and 24% older than the age of 70 years.

Clinical Features

Polyneuropathy may occur at any age, although particular syndromes are more likely to occur in certain age groups. Charcot-Marie-Tooth (CMT) disease, for example, often begins in childhood or adolescence, whereas neuropathy associated with paraproteinemia is seen more frequently with increasing age. The onset and progression differ; the Guillain-Barré syndrome (GBS), tick paralysis, and porphyria begin acutely and may remit. Others, such as vitamin B_{12} deficiency or carcinomatous neuropathy, begin insidiously and progress slowly. Still others, such as chronic inflammatory demyelinating polyneuropathy (CIDP), may begin acutely or insidiously and then progress with remissions and relapses.

The myelin sheaths or the motor or sensory axons or neurons themselves may be predominantly affected, or the neuropathy may be mixed, axonal, or demyelinating. Most polyneuropathies, especially those with primary demyelination, affect both motor and sensory functions. A predominantly motor polyneuropathy is seen in lead toxicity, dapsone or *n*-hexane intoxication, tick paralysis, porphyria, some cases of GBS, and multifocal motor neuropathy (MMN). Sensory neuropathy is divided into loss of large-diameter and small-diameter nerve fibers, although a combination of fiber types is most typical. Predominantly small-fiber neuropathy, often with concomitant autonomic dysfunction, is seen in diabetes mellitus, amyloidosis, Fabry disease, and lepromatous leprosy. Less prevalent, predominant large-fiber neuropathy occurs with thallium poisoning, paraneoplastic ganglioneuritis, Sjögren disease, pyridoxine (vitamin B_6) toxicity, and syphilis. Predominant involvement of the autonomic system can be seen in acute or chronic autonomic neuropathy or in amyloidosis.

Symptoms of polyneuropathy include distal pain, paresthesias, weakness, and sensory loss. Pain may be spontaneous or elicited by stimulation of the skin and may be sharp or burning. Paresthesias are usually described as numbness (a dead sensation), tingling, buzzing, stinging, burning, or a feeling of constriction. Lack of pain perception may result in repeated traumatic injuries with degeneration of joints (*arthropathy* or *Charcot joints*) and in chronic ulcerations.

Weakness is greatest in distal limb muscles in most neuropathies; there may be paralysis of the intrinsic foot and hand muscles with footdrop or wrist-drop. Tendon reflexes are often lost, especially in demyelinating neuropathy. In severe polyneuropathy, the patient may become quadriplegic and respirator dependent. The cranial nerves may be affected, particularly in GBS and diphtheritic neuropathy. Cutaneous sensory loss appears in a stocking-and-glove distribution. All modes of sensation

may be affected, or there may be selective impairment of "large" myelinated fiber functions (position and vibratory sense) or "small" unmyelinated fiber functions (pain and temperature perception). Often, detection of painful stimuli is impaired with a delayed and greater than normal reaction. Inappropriate pain perception is often paradoxically present despite loss of pain fibers.

Involvement of autonomic nerves may cause miosis (small pupil), Adie pupils, anhidrosis (impaired sweating), orthostatic hypotension, sphincter disturbance, gastrointestinal dysmotility, impotence, and vasomotor abnormalities; these may occur without other evidence of neuropathy but are more commonly seen in association with symmetric distal polyneuropathy. Diabetes mellitus is the most common cause. Amyloidosis causes notably severe autonomic neuropathy. The majority of neuropathy types produce distal impairment of sweating, vasomotor reflexes, and local influences that help produce the typical trophic signs in the feet of neuropathy patients. Distal loss of sweating may induce symptomatic excessive sweating proximally as a compensatory response.

In *mononeuropathy multiplex*, focal motor, sensory, and reflex changes are restricted to areas innervated by specific nerves. When multiple distal nerves are affected in mononeuropathy multiplex, the pattern may coalesce into more symmetric involvement suggesting polyneuropathy. The most frequent causes of mononeuropathy multiplex are vasculitic neuropathy, diabetes mellitus, rheumatoid arthritis, brachial neuropathy, leprosy, or sarcoidosis. Asymmetric neuropathy is also seen in MMN with conduction block, sometimes with increased anti-GM1 antibody titers, multifocal demyelinating sensory and motor neuropathy (Lewis-Sumner syndrome), and brachial neuritis.

Superficial cutaneous nerves may be thickened and visibly enlarged secondary to Schwann cell proliferation and collagen deposition from repeated episodes of segmental demyelination and remyelination or from amyloid or polysaccharide deposition in the nerves. Hypertrophic nerves may be observed or palpated in the demyelinating form of CMT (type 1), Dejerine-Sottas neuropathy, Refsum disease, von Recklinghausen disease (neurofibromatosis), and various other disorders.

Etiology and Diagnosis

Peripheral nerve disorders may be divided into hereditary and acquired forms. The most common hereditary disorder is CMT type 1A (peroneal muscular atrophy), which is associated with duplication of the peripheral myelin protein 22 gene. Deletion of the same region produces hereditary neuropathy with liability to pressure palsies. The most commonly acquired neuropathies in the United States are associated with diabetes mellitus; selected other causes of polyneuropathy are listed in Table 91.1.

In the evaluation of a patient with peripheral neuropathy, a detailed family, social, and medical and medication history; neurologic examination; and electrodiagnostic and laboratory testing are usually necessary for diagnosis. The American Academy of Neurology has made recommendations for evaluation of distal symmetric polyneuropathy (Table 91.2). Well over 200 individual causes are known, many of which are evident from initial screening measures. Skin or nerve biopsy studies are indicated in some cases. Despite these efforts, the cause of a significant minority remains idiopathic after a comprehensive evaluation. A classification of the most common acquired and hereditary polyneuropathies and their laboratory evaluation are presented in Table 91.1.

Treatment

Treatment of patients with peripheral nerve disorders can be divided into two phases: removal or treatment of the inciting condition and symptomatic therapy. Specific treatments are considered in discussions of individual disorders.

Symptomatic treatment of polyneuropathy consists of general supportive measures, amelioration of pain, and physiotherapy. Tracheal intubation and respiratory support may be needed in GBS. The corneas are protected if significant eye closure weakness is present. The bed is kept clean and the sheets are kept smooth to prevent injury to the anesthetic skin; a special mattress can be used to prevent pressure sores. In chronic polyneuropathy with footdrop, a foot orthosis often improves gait. Treatment of neuropathic pain (see Chapter 59) and autonomic failure (see Chapter 116) are discussed elsewhere in the book.

Outcome

Polyneuropathy may be progressive or remitting, and the prognosis is affected by the extent of nerve degeneration. With removal or treatment of the inciting cause, recovery is more rapid if continuity of the nerves is maintained. Conversely, recovery may be delayed for many months or remain incomplete if significant wallerian degeneration occurs. Axonal regeneration proceeds at a rate of 1 to 2 mm/d and may be further delayed where the axons must penetrate scar tissue, injured nerve segments, or other barriers. Aberrant growth of axonal sprouts may lead to formation of persistent neuromas. After severe wallerian degeneration, there may be permanent weakness, muscular wasting, diminution of reflexes, and sensory loss. In demyelinating neuropathies, recovery is sometimes more rapid and complete because of remyelination or resolution of conduction block.

SPECIFIC ACQUIRED POLYNEUROPATHIES

Guillain-Barré Syndrome

The GBS is characterized by acute onset of peripheral and cranial nerve dysfunction. Viral respiratory or gastrointestinal infection, immunization, or surgery often precedes neurologic symptoms by 5 days to 4 weeks. Symptoms and signs include rapidly progressive symmetric weakness, loss of tendon reflexes, facial diplegia, oropharyngeal and respiratory paresis, and impaired sensation in the hands and feet. The condition worsens for several days to 3 weeks, followed by a period of stability and then gradual improvement to normal or nearly normal function. Early plasmapheresis or intravenous immunoglobulin (IVIG) (2 g/kg in divided doses) accelerates recovery and diminishes the incidence of long-term neurologic disability.

In North America and Europe, acute inflammatory demyelinating polyneuropathy accounts for over 90% of GBS. A GBS also includes acute motor axonal neuropathy (AMAN), acute motor and sensory axonal neuropathy (AMSAN), Miller Fisher syndrome, and acute autonomic and sensory neuropathies.

Epidemiology

The GBS is the most frequently acute acquired demyelinating neuropathy, with an incidence of 0.6 to 1.9 cases per 100,000 population. The incidence increases gradually with age, but the disease may occur at any age. Men and women are affected equally.

TABLE 91.1 Neuropathy Diagnosis and Laboratory Tests

Cause or Diagnosis	Manifestations	Laboratory Tests
Vitamin deficiency/excess	S, SM, SYM	Vitamin B_{12}, pyridoxine (vitamin B_6), vitamin B_1, folate, vitamin E, methylmalonic acid
Infectious		
Lyme disease	S, SM, SYM, MF, CN	Serology, PCR
HIV-1	S, SM, SYM, MF, CN	Serology, PCR
Hepatitis C	S, SM, SYM, MF, CN	Serology, PCR
Herpes zoster	S, radicular	Serology, PCR
CMV	SM, M, SYM, MF	Serology, PCR, culture
Immune Mediated		
Guillain-Barré and variants	SM, S, M, SYM, MF, CN	IgG antiganglioside antibodies (GM1, GD1a, GQ1b, GD1b), urine porphyrins
IgM antibody associated	M, MF	IgM anti-GM1, GD1a
	S, SM, SYM	IgM anti-MAG, sulfatide, GD1b, GQ1b
Monoclonal gammopathy	M, S, SM, SYM, MF	Serum immunofixation electrophoresis, quantitative immunoglobulins
Autonomic neuropathy	Autonomic dysfunction	Antinicotinic acetylcholine receptor antibodies, anti-Hu
Vasculitis	SM, S, MF, SYM	ESR, cryoglobulins, hepatitis C serology, or PCR
Sarcoidosis	SM, S, MF, SYM	ACE, chest radiograph
Celiac disease	S, SM, MF, SYM	Antigliadin, endomysial, transglutaminase antibodies
Rheumatologic diseases Sjögren syndrome Lupus Wegener granulomatosis Rheumatoid arthritis	SM, S, MF, SYM	SSA-Ro, SSB-La antibodies ANA, ANCA (PR3, myeloperoxidase), dsDNA, Ab, RNP, rheumatoid factor
Paraneoplastic		
Lung cancer	S, SYM	Anti-Hu Ab, chest radiograph/CT
Waldenström syndrome	SM, S, M, SYM, MF	Serum immunofixation electrophoresis
Myeloma	SM, M, SYM, MF	Serum and urine immunofixation electrophoresis, skeletal survey
Hereditary		
CMT-1	Demyelinating, SM, SYM, MF	DNA tests for PMP-22, MPZ, EGR2, Cx32, others
CMT-2	Axonal, SM, SYM	DNA tests for NF-L, Cx32, MPZ, others
Mitochondrial	NARP, SM, MF	Serum lactate, thymidine phosphorylase, DNA testing
Other	Axonal, S, SM, amyloid, porphyria	DNA tests for transthyretin, periaxin, urine porphyrins
Metabolic/Toxic		
Diabetes	S, SM, SYM, MF, CN	Fasting glucose, HbA_{1c}, glucose tolerance test
Renal failure	S, SM, SYM	Chem 7
Thyroid disease	S, SM, SYM, MF	TSH, T4
Heavy metal toxicity	S, SM, SYM, MF	Urine lead, mercury, arsenic, thallium

Abbreviations: Ab, antibody; ACE, angiotensin-converting enzyme; ANA, antinuclear antibody; ANCA, antineutrophil cytoplasmic antibodies; CMT-1, Charcot-Marie-Tooth type 1; CMT-2, Charcot-Marie-Tooth type 2; CMV, cytomegalovirus; CN, cranial nerve; CT, computed tomography; Cx32, connexin; dsDNA, double stranded DNA; EGR, early growth response protein; ESR, erythrocyte sedimentation rate; GM1, GD1a, ganglioside components of myelin; HbA_{1c}, hemoglobin A_{1c}; HIV-1, human immunodeficiency virus type 1; IgG, immunoglobulin G; IgM, immunoglobulin M; M, motor; MAG, myelin-associated glycoprotein; MF, multifocal; MPZ, myelin protein zero; NARP, neuropathy, ataxia, and retinitis pigmentosa; NF-L, neurofilament light chain; PCR, polymerase chain reaction; PMP, peripheral myelin protein; PR3, proteinase 3; RNP, ribonucleoprotein; S, sensory; SM, sensorimotor; SSA-Ro, Sjögren syndrome with anti-Ro antibody; SSB-La, Sjögren syndrome with anti-La antibody; SYM, symmetric; T4, thyroxine; TSH, thyroid-stimulating hormone.

The incidence increases in patients with Hodgkin disease as well as with pregnancy or general surgery.

Pathobiology

The cause of GBS is incompletely understood. There is evidence that it is immune mediated. There is inflammatory pathology and patients improve with immunomodulatory therapy. A disease with similar clinical features (ie, similar pathologic, electrophysiologic, and cerebrospinal fluid [CSF] alterations) can be induced in experimental animals by immunization with whole peripheral nerve, peripheral nerve myelin, or, in some species, peripheral nerve myelin P2 basic protein or galactocerebroside. An important first step in autoimmune disease is the impairment of self-tolerance, and there is evidence that this

TABLE 91.2 American Academy of Neurology Recommendations for Testing for Distal Symmetric Polyneuropathy[a]

Basic Laboratory Evaluation for Distal Symmetric Neuropathy
CBC, ESR, or CRP
Vitamin B_{12}[b] and if vitamin B_{12} is low normal, metabolites, including methylmalonic acid and/or homocysteine[b]
Comprehensive metabolic panel, including fasting blood glucose,[b] glucose tolerance test[b] if indicated to look for impaired glucose tolerance
Serum protein immunofixation electrophoresis[b]
Urine analysis; urine electrophoresis
Inquire about drugs and toxins
Other Laboratory Testing That May Be Performed in Selected Patients
ANA, rheumatoid factor, anti-Ro/SSA, anti-La/SSB, ANCA, cryoglobulins
Campylobacter jejuni, CMV, hepatitis panel (B and C), HIV, Lyme antibodies, herpesviruses tests, West Nile virus tests, CSF analysis
Antigliadin; IgA transglutaminase antibodies; endomysial antibodies; vitamins E, B_1, and B_6
Serum ACE, CSF analysis with CSF ACE
Arsenic, lead, mercury, thallium
Antiganglioside antibodies (GM1, GD1a, GD1b, GD3, GQ1b, GT1b), anti-MAG, paraneoplastic antibodies (anti-Hu, anti-CV2), CSF oligoclonal bands
Molecular tests for Charcot-Marie-Tooth, HNPP, familial amyloidosis
Skeletal survey; computed tomography or MRI of chest, abdomen, or pelvis; ultrasound of abdomen and pelvis; PET, CSF cytology

Abbreviations: ACE, angiotensin-converting enzyme; ANA, antinuclear antibody; ANCA, antineutrophil cytoplasmic antibodies; CBC, complete blood count; CMV, cytomegalovirus; CRP, C-reactive protein; CSF, cerebrospinal fluid; ESR, erythrocyte sedimentation rate; HIV, human immunodeficiency virus; HNPP, hereditary neuropathy with tendency to pressure palsy; IgA, immunoglobulin A; MAG, myelin-associated glycoprotein; MRI, magnetic resonance imaging; PET, positron emission tomography; SSA, Sjögren syndrome with anti-Ro antibody; SSB, Sjögren syndrome with anti-La antibody.
[a]Data from England JD, Gronseth GS, Franklin G, et al. Practice parameter: evaluation of distal symmetric polyneuropathy: role of laboratory and genetic testing (an evidence-based review). *Neurology*. 2009;72:185-192.
[b]Tests with highest yield.

occurs by molecular mimicry in two forms of GBS, AMAN, and Miller Fisher syndrome, with cross-reactive epitopes between *Campylobacter jejuni* and peripheral nerve. When GBS is preceded by a viral infection, there is no evidence of direct viral infection of peripheral nerves or nerve roots.

Clinical Features

The GBS often appears days to weeks after symptoms of a viral upper respiratory or gastrointestinal infection. Usually, the first neurologic symptoms are a result of symmetric limb weakness, often with paresthesia. In contrast to most other neuropathies, proximal muscles are sometimes initially affected more than distal muscles. Occasionally, facial, ocular, or oropharyngeal muscles are affected first; more than 50% of patients have facial diplegia, and dysphagia and dysarthria develop in a similar number. Some patients require mechanical ventilation. Tendon reflexes may be normal for the first few days but are then lost. The degree of sensory impairment varies. In some patients, all sensory modalities are preserved; others have marked diminution in perception of joint position, vibration, pain, and temperature in stocking-and-glove distribution. Patients occasionally exhibit papilledema, sensory ataxia, and transient extensor plantar responses. Autonomic dysfunction, including orthostatic hypotension, labile blood pressure, tachyarrhythmia, and bradyarrhythmia or resting tachycardia is frequent in more severe cases and an important cause of morbidity and mortality. Many have muscle tenderness, and the nerves may be sensitive to pressure, but there are no signs of meningeal irritation such as nuchal rigidity.

Variants

The AMAN is a variant of GBS. There is motor axonal degeneration and little or no demyelination or inflammation. Despite the axonal involvement, recovery is similar to the demyelinating form. An AMAN may follow infection with *C jejuni*, *Mycoplasma pneumoniae*, or parenteral injection of gangliosides.

The *Miller Fisher syndrome* is characterized by gait ataxia, areflexia, and ophthalmoparesis; pupillary abnormalities are sometimes present. It is considered a variant of GBS because it is often preceded by respiratory infection, it progresses for weeks and then improves, and CSF protein content is increased. There is no limb weakness, however, and nerve conductions are generally normal; however, H reflexes may be affected. In some cases, MRI shows brainstem hyperintense lesions.

Other GBS variants include *AMSAN*, acute sensory neuropathy or neuronopathy, and acute autonomic neuropathy or pandysautonomia (see Chapter 116).

Diagnosis and Differential Diagnosis

The characteristic history of subacute development of symmetric motor or sensorimotor neuropathy after a viral illness, delivery, or surgery, together with compatible electrophysiology and an elevated CSF protein content with normal cell count, defines GBS.

In the past, the principal diseases to be differentiated from GBS were diphtheritic polyneuropathy and acute poliomyelitis. Both are now rare in the United States. Diphtheritic polyneuropathy can usually be distinguished by the long latency period between the respiratory infection and onset of neuritis, the frequency of paralysis of accommodation, and the relatively slow evolution of symptoms. Acute anterior poliomyelitis was distinguished by asymmetry of paralysis, signs of meningeal irritation, fever, and CSF pleocytosis. Acute West Nile viral infection, however, can lead to a similar picture. Acute encephalitis is the most common West Nile neurologic manifestation, but an acute paralytic syndrome is the next most frequent. Asymmetric or monomelic weakness is characteristic, but some cases develop in a GBS-like manner. Some cases have a flulike prodrome without notable encephalitis. Occasionally, patients with HIV infection have a disorder identical to GBS. Porphyric neuropathy resembles GBS clinically but is differentiated by normal CSF protein, recurrent abdominal crisis, mental symptoms, onset after exposure to barbiturates or other drugs, and high urinary levels of δ-aminolevulinic acid and porphobilinogen. Development of a GBS-like syndrome during prolonged parenteral feeding should raise the possibility of hypophosphatemia-induced neural dysfunction. Toxic neuropathies caused by *n*-hexane inhalation or thallium or arsenic ingestion may begin acutely or subacutely. Botulism may be difficult to discriminate on clinical grounds from purely motor forms of GBS, but ocular muscles and the pupils are frequently affected. Electrophysiologic tests in botulism reveal normal nerve conduction velocities and a facilitating

response to repetitive nerve stimulation. Tick paralysis, which occurs almost exclusively in children, should be excluded by careful scalp examination.

Laboratory Data

The CSF protein content is elevated in most patients with GBS but may be normal in the first few days after onset. The CSF cell count is usually normal, but some patients with otherwise typical GBS have 10 to 100 mononuclear cells/μL of CSF. Antecedent infectious mononucleosis, cytomegalovirus (CMV) infection, viral hepatitis, human immunodeficiency virus (HIV) infection, or other viral diseases may be documented by serologic studies. Increased titers of immunoglobulin G (IgG) or immunoglobulin A (IgA) antibodies to GM1 or GD1a gangliosides may be found in the axonal form of GBS; anti-GQ1b antibodies are closely associated with the Miller Fisher syndrome.

Electrophysiology and Pathology

Nerve conduction velocities are reduced in GBS, but values may be normal early in the course. Distal motor latencies may be prolonged. Because of demyelination of nerve roots, minimal F-wave latency is often increased or responses are absent from proximal conduction block. Conduction slowing may persist for months or years after clinical recovery. In general, the severity of neurologic abnormality is not related to the degree of conduction slowing but is related to the extent of conduction block or axonal loss. Long-standing weakness is most apt to occur when compound motor action potential amplitudes are reduced to less than 20% of normal.

Histologically, GBS is characterized by focal segmental demyelination (Fig. 91.1) with perivascular and endoneurial infiltrates of lymphocytes and monocytes or macrophages (Fig. 91.2). These lesions are scattered throughout the nerves, nerve roots, and cranial nerves. In particularly severe lesions, there is both axonal degeneration and segmental demyelination. During recovery, remyelination occurs, but the lymphocytic infiltrates may persist.

Treatment

Early plasmapheresis LEVEL 1[1,2] or IVIG LEVEL 1[3] therapy has proved useful in patients with GBS. Glucocorticoid administration does not shorten the course or affect the prognosis. Mechanically assisted ventilation is sometimes necessary, and precautions against aspiration of food or stomach contents must be taken if oropharyngeal muscles are affected. Exposure keratitis must be prevented in patients with facial diplegia.

FIGURE 91.1 Focal demyelination in acute Guillain-Barré syndrome. (Courtesy of Dr. Arthur Asbury.)

FIGURE 91.2 Diffuse mononuclear infiltrate in peripheral nerve in Guillain-Barré syndrome. (Courtesy of Dr. Arthur Asbury.)

Outcome

Symptoms are usually most severe within 1 week of onset but may progress for 3 weeks or more. Death is uncommon but may follow aspiration pneumonia, pulmonary embolism, intercurrent infection, or autonomic dysfunction. The rate of recovery varies. In some, it is rapid, with restoration to normal function within a few weeks. In most, recovery is slow and not complete for many months. Recovery is accelerated by early institution of plasmapheresis or IVIG therapy. In untreated series, about 35% of patients have permanent residual hyporeflexia, atrophy, and weakness of distal muscles or facial paresis. A biphasic illness, with partial recovery followed by relapse, is present in fewer than 10% of patients. Recurrence after full recovery occurs in about 2%.

Chronic Inflammatory Demyelinating Polyneuropathy

A CIDP may begin insidiously or acutely, as GBS, and then follow a chronic progressive or relapsing course. It often follows nonspecific viral infections, although less often than in GBS. Segmental demyelination and lymphocytic infiltrates are present in peripheral nerves, and a similar disease can be induced in experimental animals by immunization with peripheral nerve myelin. The CSF protein content is often increased but less consistently than in GBS. An infantile form of CIDP begins with hypotonia and delayed motor development. Nerves may become enlarged because of Schwann cell proliferation and collagen deposition after recurrent segmental demyelination and remyelination (Figs. 91.3 and 91.4).

In contrast to GBS, glucocorticoid therapy is often beneficial. The CIDP is also responsive to plasmapheresis LEVEL 1[4] or IVIG LEVEL 1.[5] Immunosuppressive drug therapy may be effective in resistant cases. Research criteria for the diagnosis of CIDP have been recommended, but there is no specific test, and the diagnosis is often made on clinical grounds. A predominantly sensory or distal form of CIDP and a multifocal form (the Lewis-Sumner syndrome) have been described. Tests for HIV-1, monoclonal paraproteins, antibodies to myelin-associated glycoprotein, and, occasionally, CMT type 1 or hereditary neuropathy with liability

FIGURE 91.3 Semithin section showing multifocal thinly myelinated fibers in a patient with chronic inflammatory demyelinating polyneuropathy (magnification ×600).

to pressure palsy are performed in suspected patients to evaluate possible causes of demyelinating neuropathy.

Multifocal Motor Neuropathy

An MMN is a clinical syndrome of lower motor neuron dysfunction. Typically, there is weakness, wasting, and fasciculation with preserved or absent tendon reflexes. The findings are typically asymmetric and affect the arms and hands more than the legs.

FIGURE 91.4 Teased fiber showing demyelination in a patient with chronic inflammatory demyelinating polyneuropathy (magnification ×400).

Electrophysiologic evidence of denervation is accompanied by the defining abnormality, physiologic evidence of multifocal motor conduction block, at sites other than typical compression sites. Other signs of demyelination are also described; conduction block is not present in all patients, including some with positive antibody titers. The MMN is associated with increased titers of immunoglobulin M (IgM) anti-GM1 in approximately 60% of patients; less frequently, anti-GD1a antibodies are found. The clinical syndrome also occurs in patients with normal anti-GM1 antibody titers. It is important to distinguish these patients from patients with typical motor neuron disease because the weakness of MMN is potentially reversible with IVIG LEVEL 1[6] or immunosuppressive drug therapy.

Sensory Neuronopathy and Neuropathy

Sensory neuropathy may result from primary involvement of the sensory root ganglia, as in ganglioneuritis or sensory neuronitis, or the nerve may be directly affected as in distal sensory neuropathy. *Ganglioneuritis* may be acute or subacute in onset and is characterized by numbness, paresthesia, and pain that can be distal or radicular or can involve the entire body, including the face. Ataxia and autonomic dysfunction may be evident. Small- or large-fiber sensation or both may be affected to varying degrees. Tendon reflexes may be present or absent, and strength is normal. The disease may be self-limiting or chronic, with relapses or slow progression. Motor nerve conduction velocities are normal or near normal, but sensory potentials are reduced in amplitude or absent. Routine electrophysiologic studies may be normal if the disease is mild or if only small fibers are affected. The CSF protein content is normal or slightly elevated. Response to glucocorticoids or immunosuppressive therapy is variable. Pathologic studies of spinal root ganglia show inflammatory infiltrates with a predominance of T cells and macrophages. Some patients have sicca or Sjögren syndrome with anti-Ro and anti-La antibodies.

Several autoantibodies to peripheral nerve antigens are associated with sensory neuropathy. Some patients with sensory axonal neuropathies have monoclonal or polyclonal IgM anti-sulfatide antibodies, and monoclonal IgM autoantibodies with anti-GD1b and disialosyl ganglioside antibody activity have been associated with large-fiber sensory neuropathy. Other causes of sensory neuropathy include HIV-1 infection, vitamin B_6 deficiency or toxicity, celiac disease, paraneoplastic neuropathy, amyloidosis, and toxic neuropathy.

Idiopathic Autonomic Neuropathy

This condition is characterized by sympathetic, parasympathetic, or enteric nerve dysfunction. Acute, subacute, and chronic forms are known and discussed in Chapter 116.

Vasculitic and Cryoglobulinemic Neuropathies

Vasculitic neuropathy is manifested as mononeuritis multiplex or distal symmetric polyneuropathy. Nerve conduction studies may show electrical inexcitability of nerve segments distal to an injury caused by vascular occlusion. If some nerve fascicles are spared, conduction proceeds at a normal rate, but summated response amplitude is diminished. The diagnosis of peripheral nerve involvement may be established by nerve and muscle

FIGURE 91.5 Necrotizing vasculitis (magnification ×200).

biopsies (Fig. 91.5), which typically show inflammatory cell infiltrates and necrosis of blood vessel walls. The biopsy specimen, however, may show only axonal degeneration if vasculitis produced a nerve injury that is proximal to the biopsy site or if no affected vessels are encountered in the specimen.

Vasculitis may be confined to the peripheral nerves or may be associated with systemic disease, such as polyarteritis or cryoglobulinemia. The most common systemic cause of vasculitic neuropathy is polyarteritis nodosa, which may cause purpuric skin lesions, renal failure, Raynaud phenomenon, constitutional symptoms, and sometimes mixed polyclonal cryoglobulinemia; hepatitis B or C virus or HIV infection may be found. Cryoglobulins are immunoglobulins that precipitate in the cold and are classified as types I to III. Type I contains a monoclonal immunoglobulin only, type II contains both monoclonal and polyclonal immunoglobulins, and type III contains mixed polyclonal immunoglobulins. Types I and II are associated with plasma cell dyscrasia, and type III may be associated with polyarteritis nodosa and hepatitis B or C infection. Cryoglobulin testing samples must be kept warm to prevent precipitation prior to laboratory analysis.

Other causes of vasculitic neuropathy include the Churg-Strauss syndrome with asthma and eosinophilia; Sjögren syndrome with xerophthalmia, xerostomia, and anti-Ro and anti-La antibodies; and Wegener granulomatosis with necrotizing granulomatous lesions in the upper or lower respiratory tract, glomerulonephritis, and antineutrophil cytoplasmic antibodies. Less commonly, vasculitic neuropathy is seen in rheumatoid arthritis, systemic lupus erythematosus, and systemic sclerosis. Vasculitis may respond to therapy with prednisone (60 mg every day) and cyclophosphamide (1 g/m^2 every month × 6 months). Plasmapheresis is also useful in the treatment of cryoglobulinemia.

Neuropathies Associated With Myeloma and Nonmalignant Immunoglobulin G or Immunoglobulin A Monoclonal Gammopathies

Peripheral neuropathy is found in approximately 50% of patients with osteosclerotic myeloma and IgG or IgA monoclonal gammopathies. Some patients have the POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes) or Crow-Fukase syndrome with hyperpigmentation of skin, edema, excessive hair growth, hepatosplenomegaly, papilledema, elevated CSF protein content, hypogonadism, and hypothyroidism. The POEMS syndrome is sometimes associated with nonosteosclerotic myeloma or with nonmalignant monoclonal gammopathy. The IgG or IgA light-chain type is almost always λ. Electrophysiologic and pathologic abnormalities are consistent with demyelination and axonal degeneration; the patterns may resemble CIDP.

Malignant or nonmalignant IgG or IgA monoclonal gammopathy may also be associated with neuropathy in primary amyloidosis, in which fragments of the monoclonal light chains are deposited as amyloid in peripheral nerve, and in types I and II cryoglobulinemia, in which the monoclonal immunoglobulins are components of the cryoprecipitates.

The significance of IgG or IgA monoclonal gammopathies is uncertain in the absence of myeloma, POEMS syndrome, amyloidosis, or cryoglobulinemia. Nonmalignant monoclonal gammopathies are found more frequently in patients with neuropathy of otherwise unknown etiology; however, they are also present in approximately 1% of normal adults, and the frequency increases with age or in chronic infections or inflammatory diseases, so the association with neuropathy in some cases could be coincidental. Other causes of neuropathy, particularly inflammatory conditions such as CIDP, should be considered. In cases of myeloma, irradiation, chemotherapy, or bone marrow transplantation may be beneficial. Some patients with neuropathy associated with IgG and IgA monoclonal proteins of undetermined significance improve with plasmapheresis.

Neuropathies Associated With Immunoglobulin M Monoclonal Antibodies That React With Peripheral Nerve Glycoconjugate Antigens

In several syndromes, peripheral neuropathy is associated with polyclonal or monoclonal IgM autoantibodies that react with glycoconjugates in peripheral nerve. The IgM antibodies that react with myelin-associated glycoprotein are associated with a chronic demyelinating sensorimotor neuropathy. Pathologic studies show deposits of the monoclonal IgM and complement on affected myelin sheaths (Fig. 91.6) and passive transfer of the autoantibodies in experimental animals reproduces the neuropathy. Treatment consisting of plasmapheresis and chemotherapy to reduce autoantibody concentrations, or IVIG, frequently results in clinical improvement.

Other syndromes associated with monoclonal or polyclonal IgM autoantibodies include the following: MMN or lower motor neuron syndrome–associated anti-GD1a ganglioside antibodies, large-fiber sensory neuropathy with anti-GD1b and disialosyl ganglioside antibodies, and axonal sensory neuropathy associated with antisulfatide antibodies. Antisulfatide antibodies typically are associated with small-fiber or small- and large-fiber neuropathy, but 25% of cases demonstrate a CIDP-like demyelinating neuropathy.

Progressive Inflammatory Neuropathy (Among Swine Slaughterhouse Workers)

Beginning in 2007, 24 patients who worked in three different pork-processing plants developed an inflammatory neuropathy

FIGURE 91.6 Patient with an immunoglobulin M (IgM) κ monoclonal protein and anti–myelin-associated glycoprotein neuropathy showing IgM (A) and κ (B) staining on immunofluorescence.

that resembled CIDP. Those affected worked at the head table, where a compressed air device was used to extract pig brains. Patients had a polyradiculoneuropathy with weakness and pain. Some patients had facial neuropathy. The symptoms progressed from 8 to 213 days. The CSF protein was elevated in the majority from 63 to 210 mg/dL, with pleocytosis in only one patient. Nerve conduction studies showed demyelinating and axonal changes. Serum from the patients demonstrated IgG staining of neural tissue.

Amyloid Neuropathy

Amyloid is an insoluble extracellular aggregate of proteins that forms in nerve or other tissues when any of several proteins is produced in excess. The two principal forms of amyloid protein that cause neuropathy are immunoglobulin light chains in patients with primary amyloidosis and plasma cell dyscrasias and transthyretin in hereditary amyloidosis. The syndrome is often that of a painful, small-fiber sensory neuropathy with progressive autonomic failure, symmetric loss of pain and temperature sensations with spared position and vibratory senses, carpal tunnel syndrome, or some combination of these symptoms. The diagnosis of amyloid neuropathy can be established by histologic demonstration of amyloid in nerve (Fig. 91.7), followed by immunocytochemical characterization of the deposits with the use of antibodies to immunoglobulin light chains or transthyretin. The responsible protein forming amyloid can also be detected by microdissection and mass spectrometry. Mutation of the transthyretin gene is detected by DNA analysis. The prognosis is poor if untreated. Other hereditary amyloidosis causes, such as apolipoprotein A1 and gelsolin, lead to less severe and less frequent neuropathy. Electrophoresis of serum and urine with immunofixation can assist in the diagnosis of primary amyloid neuropathy. Liver transplantation has been reported to be beneficial for hereditary amyloidosis, and high-dose chemotherapy followed by bone marrow transplantation has been reported to help some patients with primary amyloidosis. Medications that stabilize the transthyretin tetramer and decrease the formation of amyloid, including tafamidis 20 mg every day LEVEL 1[7] and diflunisal 250 mg twice a day LEVEL 1,[8] may improve the neuropathy. The RNA silencers, which block the production of transthyretin, including patisiran LEVEL 1[9] and inotersen LEVEL 1,[10] can stop the progression of the neuropathy and some patients actually improve.

Neuropathy Associated With Carcinoma (Paraneoplastic Neuropathy)

Both direct and indirect effects of malignant neoplasms on the peripheral nervous system are recognized. In some patients, the nerves or nerve roots are compressed or infiltrated by neoplastic cells. In others, there is no evidence of damage to the nerves by

FIGURE 91.7 Amyloid neuropathy. Massive deposits of endoneurial amyloid compress nerve fiber bundles. (Courtesy of Dr. Arthur Asbury.)

the neoplasm, and dietary deficiency or metabolic, toxic, or immunologic factors may be responsible.

The most characteristic paraneoplastic disorder is a sensory neuropathy of subacute onset associated with small cell carcinoma of the lung. Electrodiagnostic studies reveal loss of sensory-evoked responses. Autoantibodies against the Hu antigen (antineuronal nuclear or ANNA-1) are characteristic, and postmortem studies show loss of neurons, deposition of antibodies, and inflammatory cells in dorsal root ganglia.

Less consistently associated with carcinoma is a distal sensorimotor polyneuropathy without specific features. Nerve biopsy may reveal infiltration by tumor cells, axonal degeneration, or demyelination. A primarily motor syndrome of subacute onset rarely occurs in Hodgkin disease and other lymphomas. In these patients, the predominant lesion is degeneration of anterior horn cells, but demyelination, perivascular mononuclear cell infiltrates, and alterations in Schwann cell morphology in ventral roots are also observed.

The diagnosis of malignancy should be suspected in a middle-aged or elderly patient with a subacute sensory neuropathy or polyradiculopathy of obscure cause, particularly with weight loss. The course is often progressive unless the primary malignancy is successfully treated. The CSF examination for malignant cells is valuable in the diagnosis of malignant meningeal infiltration. In some instances of meningeal infiltration, radiotherapy or intrathecal chemotherapy may be valuable.

Hypothyroid Neuropathy

Entrapment neuropathies are relatively common in patients with hypothyroidism, probably because acid mucopolysaccharide protein complexes (mucoid) are deposited in the nerve. Painful paresthesia in the hands and feet is the most common symptom of hypothyroidism. Weakness is not a feature. Tendon reflexes are reduced or absent and, when present, may show the characteristic delayed or "hung-up" response. Direct muscle percussion produces transient mounding of the underlying skin and muscle (myoedema). Nerve conduction studies show mild slowing of motor nerve conduction and decreased sensory response amplitude. Morphologic studies show evidence of demyelination, axonal loss, and excessive glycogen within Schwann cells. The CSF protein content is often more than 100 mg/dL. Rarely, dysfunction of cranial nerves IX, X, and XII causes hoarseness and dysarthria, probably as a result of local myxedematous infiltration of the nerves. The peripheral neuropathy may occur before there is laboratory evidence of hypothyroidism. Once identified, thyroid replacement causes clinical, electrophysiologic, and morphologic improvement.

Acromegalic Neuropathy

Entrapment neuropathy is also relatively common in patients with acromegaly. Rarely, acromegalic patients note distal paresthesia, but in contrast to myxedematous patients, weakness may be severe and peripheral nerves may be palpable. There is a significant correlation between total exchangeable body sodium and the severity of the neuropathy. The nerves are enlarged because there is increased endoneurial and perineurial connective tissue, perhaps stimulated by increased levels of somatomedin C (insulin-like growth factor 1). Tendon reflexes are reduced. Nerve conduction velocities are mildly slow with low evoked response amplitudes.

Hyperthyroid Neuropathy

Hyperthyroidism can produce a syndrome consisting of diffuse weakness and fasciculations with preserved or hyperactive tendon reflexes, resembling amyotrophic lateral sclerosis. However, the symptoms and signs disappear with treatment of the toxic state. No convincing pathologic studies have established the presence of chronic sensorimotor neuropathy with hyperthyroidism.

Celiac Neuropathy

Celiac disease is a chronic inflammatory enteropathy with a prevalence of 1:250. Peripheral neuropathy is the most common neurologic condition associated with celiac disease. It is not thought to be a result of nutritional deficiency. In over half of patients with celiac neuropathy, gastrointestinal complaints are absent. Celiac disease is caused by exposure to ingested gluten, the storage proteins of wheat, and similar proteins found in barley and rye. Patients have specific HLA-DQ2 and HLA-DQ8 alleles.

The neuropathy is usually predominantly sensory. Multifocal involvement is frequent, with early involvement of the hands and face, although some have a length-dependent pattern. A small-fiber neuropathy is more common initially, but a sensorimotor polyneuropathy is also seen. Diagnosis is suspected with elevated gliadin or transglutaminase antibodies and confirmed by a duodenal biopsy demonstrating inflammation, crypt hyperplasia, and villous atrophy in the small intestine mucosa. Gastrointestinal symptoms improve with a gluten-free diet. The symptoms of peripheral neuropathy have improved in some, but not all, patients on a gluten-free diet. Only small amounts of gluten exposure can trigger an active immune response.

Uremic Neuropathy

Peripheral neuropathy is only one of the neuromuscular syndromes associated with chronic renal failure. Restless legs, cramps, and muscle twitching may be early manifestations of peripheral nerve disease. Peripheral neuropathy is present in 70% of patients with chronic renal failure, but most are subclinical and are identified only by nerve conduction studies. Symptoms include painful dysesthesia and glove-stocking loss of sensation as well as weakness of distal muscles. Electrodiagnostic studies show a sensorimotor neuropathy with axonal features. Pathologic studies confirm the axonopathy. Secondary demyelination may result from axonal loss. Dialysis rarely reverses the neuropathy but may stabilize symptoms; peritoneal dialysis is more effective than hemodialysis. Serial nerve conduction studies can measure the effectiveness of hemodialysis but is no longer routinely used. Renal transplantation often resolves the neuropathy following surgery.

Mononeuropathy, particularly carpal tunnel syndrome, often appears distal to an implanted arteriovenous fistula, suggesting ischemia as a possible mechanism. Distal ischemia from implanted bovine shunts may cause a more severe ischemic neuropathy in the median, ulnar, and radial nerves, possibly from excessive arteriovenous shunting. Chronic hemodialysis (>10 y) causes excessive accumulation of β_2-microglobulin (generalized amyloidosis), another possible cause of carpal tunnel syndrome and uremic polyneuropathy.

The cause of uremic neuropathy is uncertain. An accumulation of a toxic metabolite is most likely, but its identity is unknown. A 2- to 60-kDa molecular weight compound in the plasma of uremic patients induced an axonal neuropathy in experimental animals.

Neuropathy Associated With Hepatic Disease

Peripheral neuropathy is rarely associated with primary diseases of the liver. A painful sensory neuropathy is seen with primary biliary cirrhosis, probably caused by xanthoma formation in and around nerves. Electrodiagnostic studies may be normal, or the amplitude of the sensory-evoked response may be low or absent. Nerve biopsy shows loss of small-diameter nerve fibers. Sudanophilic material is seen in cells of the perineurium. Treatment is directed at pain control. Tricyclic antidepressants or anticonvulsants may relieve paresthesia.

Infectious diseases of the liver may also be associated with peripheral neuropathy. Viral hepatitis (especially hepatitis C associated with cryoglobulinemia), HIV or CMV infection, and infectious mononucleosis may be associated with acute demyelinating neuropathy (GBS), chronic demyelinating neuropathy, or mononeuropathy multiplex. Immunologically mediated diseases such as polyarteritis and sarcoidosis may also cause liver abnormalities and mononeuropathy multiplex.

Peripheral neuropathy is often seen with toxic liver disease or hepatic metabolic diseases such as acute intermittent porphyria and abetalipoproteinemia.

Neuropathies Associated With Infection

Neuropathy of Leprosy

Direct infiltration of small-diameter peripheral nerve fibers by *Mycobacterium leprae* causes the neuropathy of leprosy. It was formerly the most common neuropathy in the world, although it is now overtaken by diabetic neuropathy, largely because of a recent sharp decline in incidence in many endemic areas, especially India. From 2002 to 2007, the incidence globally had dramatically decreased at an average rate of nearly 20% per year based on World Health Organization reports. In the United States, the disease is less endemic but is seen in immigrants from India, Southeast Asia, and Central Africa.

Peripheral nerves are affected differently in tuberculoid and lepromatous forms. In tuberculoid leprosy, there are small hypopigmented areas with superficial sensory loss, and the underlying subcutaneous sensory nerves may be visibly or palpably enlarged. Large nerve trunks, such as the ulnar, fibular, facial, and posterior auricular nerves, may be enmeshed in granulomas and scar tissue. Endoneurial caseation necrosis may occur. The clinical picture is one of mononeuritis or mononeuritis multiplex.

In lepromatous leprosy, Hansen bacilli proliferate in large numbers within Schwann cells and macrophages in the endoneurium and perineurium of subcutaneous nerve twigs (Fig. 91.8), particularly in cool areas of the body (pinnae of the ears and dorsum of the hands, forearms, and feet). Loss of cutaneous sensibility is observed in affected patches; these may later coalesce to cover large parts of the body. Position sense may be preserved in affected areas, whereas pain and temperature sensibility is lost, a dissociation similar to that in syringomyelia. Tendon reflexes are preserved.

Acute mononeuritis multiplex may appear during chemotherapy of lepromatous leprosy in conjunction with erythema nodosum. This complication is treated with thalidomide, which is also associated with neuropathy.

Treatment is designed to eradicate the bacterium and to prevent secondary immune reactions that may damage nerves.

FIGURE 91.8 Lepromatous leprous neuritis. Few myelinated fibers are scattered in fibrotic endoneurium. Abundant foam cells *(arrows)* contain *Mycobacterium leprae* bacilli when viewed at higher magnification. (Courtesy of Dr. Arthur Asbury.)

Multidrug therapy is recommended by the World Health Organization. Adult patients with paucibacillary or multibacillary disease are prescribed rifampin. For patients with multibacillary leprosy, an extra drug, clofazimine, is prescribed. Dapsone is also recommended for both paucibacillary and multibacillary adult patients. Dapsone is effective but may cause toxic motor neuropathy. Because of the dense sensory loss, painless and inadvertent traumatic injuries, such as self-inflicted burns, may occur without extreme caution to avoid trauma to the anesthetic areas.

Diphtheritic Neuropathy

Although diphtheria itself is rare, diphtheritic neuropathy occurs in approximately 20% of infected patients. *Corynebacterium diphtheriae* infects the larynx and pharynx as well as cutaneous wounds. The organisms release an exotoxin that causes myocarditis and, later, symmetric neuropathy. The neuropathy often begins with impaired visual accommodation and paresis of ocular and oropharyngeal muscles, and quadriparesis follows. Nerve conduction velocities are slow, reflecting the underlying demyelinating neuropathy. Diphtheria may be prevented by immunization, and if infection occurs, antibiotic therapy may be used. Recovery may be slow, and physiologic measures resolve after the clinical syndrome.

HIV-Related Neuropathies

Several neuropathies afflict patients infected with HIV, depending on the stage of the illness and the immunocompetence of the patient. An acute demyelinating neuropathy indistinguishable from sporadic GBS may occur early in the course of infection, often with no signs of immunodeficiency or at the time of seroconversion, as well as once AIDS develops. Sometimes, a CSF pleocytosis is present, which is not typical of GBS in non–HIV-infected patients.

Subacute demyelinating neuropathy, clinically indistinguishable from idiopathic CIDP, is usually found in HIV-positive patients before there is evidence of immunodeficiency (AIDS). The CSF protein content is increased in both idiopathic CIDP and HIV-associated demyelinating neuropathy. Steroids, plasmapheresis, and IVIG therapy have been reported to be effective treatments.

In patients who fulfill diagnostic criteria for AIDS, there is frequently a distal sensorimotor polyneuropathy with axonal

features. The syndrome is dominated by severe painful paresthesia most intensely affecting the feet. This painful neuropathy can be the most functionally disabling manifestation of AIDS. Nerve conduction studies may be normal, but reduced intraepidermal nerve fiber density is seen on skin biopsy. The exact mechanism is uncertain. The HIV infection of dorsal root ganglion neurons has been demonstrated. Because of the scarcity of neuronal infection, other causes such as toxicity of activated macrophages and cytokines and viral protein toxicity have been considered. No treatment reverses the symptoms, but symptomatic medications, such as lamotrigine or gabapentin, may help. One form of neuropathy in HIV-infected patients is the diffuse infiltrative lymphocytosis syndrome, a hyperimmune reaction to HIV infection.

Mononeuropathy multiplex can occur in HIV-infected patients at any stage of the disease, sometimes with hepatitis. When CD4 cells number fewer than 50/mm^3, the likely cause of the mononeuropathy is CMV, and prompt treatment with ganciclovir sodium (Cytovene) may be lifesaving. The CMV infection is also associated with polyradiculopathy.

The dideoxynucleotide antiretroviral medications, used to treat HIV infection, may cause painful sensory neuropathy, which is problematic to separate from primary painful HIV sensory neuropathy.

Neuropathy of Herpes Zoster

Varicella-zoster virus infection of the dorsal root ganglion produces radicular pain that may precede or follow the appearance of the characteristic skin eruption. Although primarily a sensory neuropathy, weakness from motor involvement occurs in 0.5% to 5% of infected patients. Herpes zoster (shingles) is a common phenomenon most frequent in elderly patients, cancer patients, or immunosuppressed patients. Post-rash pain (postherpetic neuralgia) usually in the same distribution as the dermatomal rash occurs in a minority, but risk increases significantly with age (50% over 70 y). For diagnosis, pain should persist for 1 to 6 months after the rash disappears. Severe acute pain, more intense rash, scarring, sensory loss, and fever increase the risk of postherpetic neuralgia. Zoster infections are also associated with GBS and CSF pleocytosis. Zoster infection often occurs in patients with HIV infection; the combination of herpes infection and focal weakness in a young person should alert the clinician to the possibility of HIV infection.

Herpes zoster may affect any level of the neuraxis, but it most often involves thoracic dermatomes and cranial nerves with sensory ganglia (V and VII). Ophthalmic herpes infection characteristically involves the gasserian ganglion and the first division of the trigeminal nerve. There may be weakness of ocular muscles and ptosis. Infection of the geniculate ganglion of the facial nerve (cranial nerve VII) causes a vesicular herpetic eruption in the external auditory meatus, vertigo, deafness, and facial weakness (Ramsay Hunt syndrome). Pain is constant and burning and may include paroxysms of very severe pain.

Treatment with acyclovir (Zovirax), 4 g/d in five doses for 7 to 10 days or other antiviral agents decreases the incidence of segmental motor neuritis and sensory axonopathy. They may also reduce the incidence of postherpetic neuralgia. Tricyclic antidepressants, opioids, anticonvulsants (pregabalin), and lidocaine patches may show symptomatic benefit, some verified in randomized clinical trials. An attenuated varicella-zoster virus vaccine is recommended in adults 60 years and older, without contraindications, to prevent the development of herpes zoster.

Lyme Neuropathy

Lyme disease is commonly diagnosed in the United States and Europe. It is caused by a tick-borne spirochete, *Borrelia burgdorferi*. The most common clinical feature of neuroborreliosis is a painful sensory radiculitis, which may appear about 3 weeks after the erythema migrans. Pain intensity varies from day to day and is often severe, jumping from one area to another and often associated with patchy areas of unpleasant dysesthesia. Onset may be subacute potentially simulating GBS but with significant CSF pleocytosis and without clear signs of demyelination. Focal neurologic signs are common and may present as cranial neuropathy (61%), limb paresis (12%), or both (16%), but detailed electrodiagnostic signs often point to mononeuropathy multiplex. The clinical pattern may appear as a mononeuropathy, plexopathy, mononeuropathy multiplex, or distal symmetric polyneuropathy. The facial nerve is frequently affected; involvement is unilateral twice as often as bilateral. Ophthalmoparesis occasionally occurs. Myeloradiculitis and chronic progressive encephalomyelitis are rare. In some, the disorder is associated with dilated cardiomyopathy. Arthralgia is common among patients in the United States but rare among Europeans (6%). The triad of painful radiculitis, predominantly cranial mononeuritis multiplex, and lymphocytic pleocytosis in the CSF is known as *Bannwarth syndrome* in Europe. Peripheral nerve biopsy shows perineurial and epineurial vasculitis and axonal degeneration. The diagnosis of neuroborreliosis is based on the presence of inflammatory CSF changes and specific intrathecal *B burgdorferi* antibodies. In some infected patients, however, no free antibodies are detectable. Antigen detection in CSF is sometimes helpful. Polymerase chain reaction technique for detecting spirochetes or spirochetal DNA is less specific. The prognosis is good after high-dose penicillin or ceftriaxone treatment. Disabling sequelae are rare and occur mainly in patients with previous CNS lesions.

Sarcoid Neuropathy

Neurologic symptoms appear in 4% of patients with sarcoidosis. Most commonly, there are single or multiple cranial nerve palsies that fluctuate in intensity. Of the cranial nerves, the seventh is most commonly affected, and, as in diabetes mellitus, the facial nerve syndrome in sarcoidosis is indistinguishable from idiopathic Bell palsy. Some cranial neuropathies in sarcoidosis result from basilar meningitis. One distinguishing feature of sarcoid mononeuropathy is a large area of sensory loss on the trunk.

Patients with sarcoidosis occasionally experience symmetric polyneuropathy months or years after the diagnosis is established. The neuropathy may be the first manifestation before the diagnosis of sarcoidosis is made. The clinical syndromes may include GBS, lumbosacral plexopathy, mononeuritis multiplex, pure sensory neuropathy, and small-fiber and autonomic neuropathy. Cranial nerve symptoms are seen in close to one-half of patients.

Nerve biopsy shows a mixture of wallerian degeneration and segmental demyelination with sarcoid granulomas in endoneurium and epineurium (Fig. 91.9). Sarcoid neuropathy may respond to steroid therapy, intravenous immune globulin, or anti–tumor necrosis factor therapy.

FIGURE 91.9 Nerve biopsy in patient with sarcoid neuropathy showing granuloma (magnification ×40).

Polyneuropathy Associated With Dietary States

Thiamine deficiency may cause two clinical syndromes: *wet beriberi*, in which congestive heart failure is the predominant syndrome, and *dry beriberi*, in which peripheral neuropathy is the predominant symptom. Patients with thiamine deficiency have severe burning dysesthesia in the feet more than in the hands, weakness and wasting of distal muscles more than of proximal muscles, trophic changes (shiny skin, hair loss), and distal sensory loss. An electromyogram and a nerve conduction studies reveal the presence of a diffuse sensorimotor peripheral neuropathy that is axonal. Axonal degeneration is also the principal finding seen on nerve biopsy specimens. Treatment of both beriberis should include parenteral B-complex vitamins followed by oral thiamine. Recovery is slow; there may be residual muscular weakness and atrophy.

Niacin (nicotinic acid) deficiency causes pellagra characterized by hyperkeratotic skin lesions. Peripheral neuropathy is usually present in niacin-deficient patients, but the neuropathy does not improve solely with niacin supplementation, likely because of multivitamin deficiency. Symptoms usually improve when additional thiamine and pyridoxine are added to the diet.

Vitamin B_{12} deficiency causes the classic clinical syndrome of subacute combined degeneration of the spinal cord. Separation of the peripheral neuropathic symptoms from spinal cord involvement is difficult. Painful paresthesias are present, but sensory ataxia with loss of vibration and joint position sense is most severe. Despite the myelopathy, tendon reflexes are often diminished or absent. Vitamin B_{12} deficiency neuropathy may be present with low normal vitamin B_{12} levels and can be established with measurement of the elevated metabolites methylmalonic acid and homocysteine.

Nitrous oxide also irreversibly inactivates cobalamin, producing the same syndrome. A single anesthetic dose in a vulnerable individual or chronic exposure usually with abuse of dental or medical sources or commercial propellants (whipped cream) may result in vitamin B_{12} deficiency. Hematologic abnormalities are usually absent in abuse cases.

Vitamin B_6 (pyridoxine) deficiency produces a peripheral neuropathy, and the most common cause of pyridoxine deficiency is ingestion of the antituberculous drug isoniazid. Isoniazid increases the excretion of pyridoxine. The resulting neuropathy affects sensory fibers more than motor fibers and is caused by axonal loss. Treatment consists of supplemental pyridoxine to compensate for the added excretion. The neuropathy can be prevented by prophylactic pyridoxine administration. Pyridoxine excess can lead to severe sensory neuropathy as well.

Vitamin E deficiency contributes to neuropathy in fat malabsorption syndromes—including abetalipoproteinemia, congenital biliary atresia, pancreatic dysfunction, and surgical removal of large portions of the small intestine. The clinical syndrome of vitamin E deficiency resembles spinocerebellar degeneration with ataxia, severe sensory loss of joint position and vibration, and hyporeflexia. Motor nerve conduction studies are normal, but sensory-evoked responses are of low amplitude or absent.

Somatosensory-evoked responses show a delay in central conduction. The electromyogram is usually normal. Serum vitamin E levels can be measured. Repletion with large oral doses is often sufficient if initiated early in the disease course.

Copper deficiency can result in a neuropathy, which is often accompanied by a myelopathy and leukopenia. Some patients develop copper deficiency from excessive use of zinc. Copper supplementation stops the progression, although recovery is often not complete.

Strachan syndrome includes visual loss, oral ulcers, skin changes, and painful neuropathy. The syndrome was originally described in Jamaican sugar workers and caused an epidemic in Cuba in 1991. A nutrient-poor diet with deficient B vitamins has been implicated.

Gastric bypass surgery is associated with subacute and sometimes severe axonal neuropathy that accompanies the rapid postoperative weight loss. Vitamin deficiency of various types is to play a crucial role.

Critical Illness Polyneuropathy

Severe sensorimotor peripheral neuropathy is seen in many patients who are critically ill, suffering from sepsis and multiple organ failure. The diagnosis may arise when a patient experiences difficulty being weaned from a ventilator after a bout of sepsis. Electrodiagnostic studies show a severe sensorimotor axonal neuropathy, but conventional studies may be unable to distinguish this entity from the more common critical illness myopathy, discussed in detail in Chapter 95. Recovery of neuronal function may occur if the underlying cause of multiple organ failure is treated successfully.

Neuropathies Caused by Heavy Metals

Arsenic

Neuropathy may follow chronic exposure to small amounts of arsenic or ingestion or parenteral administration of a large amount. Chronic exposure may occur in industries in which arsenic is released as a by-product, such as in copper or lead smelting. Because of the prevalence of these by-products, arsenic neuropathy is the most common of all heavy metal–induced neuropathies. Acute gastrointestinal symptoms, vomiting, and diarrhea occur when a toxic quantity of arsenic is ingested, but these symptoms may be absent if the arsenic is given parenterally or taken in small amounts over long periods. Acute exposure may lead to encephalopathy or coma. The evolution of polyneuropathy is much slower in chronic arsenic poisoning. Sensory symptoms

are prominent in the early stages. Pain and paresthesia in the legs may be present for several days or weeks before onset of weakness. The weakness may progress to complete flaccid paralysis of the legs and sometimes the arms, depending on the dosage. Cutaneous sensation is impaired in a stocking-and-glove distribution, with vibration and position sensation being most affected. Tendon reflexes are lost. Pigmentation and hyperkeratosis of the skin and changes in the nails (*Mees lines*) are frequently present. Arsenic is present in the urine in the acute stages of poisoning but is quickly cleared; levels persist in the hair and nails. Nerve conduction velocities may be normal or mildly diminished; the amplitude of sensory- and motor-evoked responses may be reduced. Pathologic examination of nerves shows axonal degeneration. Arsenic polyneuropathy is generally treated with a chelating agent, but the effectiveness is uncertain, given the rapid clearance in most patients.

Lead

Most toxic neuropathies cause symmetric weakness and loss of sensation in distal regions more than proximal regions, feet worse than legs. Lead neuropathy is atypical because of motor predominance and arm involvement.

Lead neuropathy occurs almost exclusively in adults. Infants poisoned with lead usually develop encephalopathy. Lead may enter the body through the lungs, skin, or gut. Occupational lead poisoning was common in earlier eras, notably in silver miners, but rarely is encountered in battery workers, painters, and pottery glazers. Accidental lead poisoning follows ingestion of lead in food or beverages or occurs in children who ingest lead paint. Lead poisoning may cause abdominal distress (lead colic). The classic description is focal wrist-drop in a radial neuropathy pattern; however, weakness is not generally limited to one nerve and produces bilateral arm weakness and wasting and lesser or later leg involvement. Footdrop is the most common leg sign. Sensory symptoms and signs are usually absent. Rarely, upper motor neuron signs occur with the lower motor neuron disorder and mimic amyotrophic lateral sclerosis. Laboratory findings include anemia with basophilic stippling of the red cells, increased serum uric acid, and slight elevation of CSF protein content. Urinary lead excretion is elevated, particularly after administration of a chelating agent. Urinary porphobilinogen excretion is also elevated, but δ-aminolevulinic acid is normal. Primary therapy is prevention of further exposure to lead. With termination of exposure and use of chelation therapy, recovery is gradual over several months.

Mercury

Mercury is used in the electrical and chemical industries. There are two forms of mercury: elemental and organic. The organic form of mercury (methyl and ethyl mercury) is most toxic to the CNS, although distal paresthesia and sensory ataxia are prominent (presumably secondary to dorsal root ganglion degeneration). Ventral roots and motor function are spared. Inorganic mercury may be absorbed through the gastrointestinal tract, and elemental mercury may be absorbed directly through the skin or lungs (it is volatile at room temperature). Elemental mercury exposure is a rare cause of weakness and axonal motor and sensory fiber loss.

Thallium

This element is used as a rodenticide and in other industrial processes. Children exposed to thallium, as with lead, may develop encephalopathy, whereas neuropathy occurs in adults. In contrast to lead poisoning, thallium neuropathy primarily affects sensory and autonomic fibers. Severe disturbing dysesthesia appears acutely, and diffuse alopecia is a characteristic feature. Signs of cardiovascular autonomic neuropathy are sometimes delayed and recover slowly. Electrophysiologic findings are consistent with an axonal neuropathy.

Other Chemicals

Acrylamide monomer is used to prepare polyacrylamide. It is used in chemical laboratories and for the treatment of liquid sewage. Exposure to the monomer produces a distal sensorimotor neuropathy that may be associated with trophic skin changes and a mild dementia. Polyacrylamides, however, are not neurotoxic. Carbon disulfide is rarely inhaled in industrial settings. Exposure may lead to sensorimotor axonal neuropathy.

Many organophosphates, used in insecticides and rodenticides, are acetylcholinesterase inhibitors and may cause delayed neuropathy. The clinical and electrophysiologic features are similar to those of neuropathies caused by chemotherapeutics. Some, however, affect the CNS, as well as peripheral nerves, and some have certain specific features. *Triorthocresyl phosphate* (Jamaica ginger or jake), an adulterant used in illegal liquor (moonshine) and as a cooking oil contaminant, was responsible for neuropathy epidemics. *Dimethylaminopropionitrile*, which is used to manufacture polyurethane foam, causes urologic dysfunction and sensory loss localized to sacral dermatomes. Exposure to *methylbromide*, an insecticide, results in a mixture of pyramidal tract, cerebellar, and peripheral nerve dysfunction. Accidental ingestion of *pyriminil*, a rat poison marketed under the name Vacor, gives rise to an acute severe distal axonopathy with prominent autonomic involvement accompanied by acute diabetes mellitus secondary to necrosis of pancreatic β cells.

Drugs of abuse may lead to neuropathy, notably *n*-hexane and methyl-*N*-butyl ketone, found in widely available household solvents, fuels, and cleaning agents. Inhalation of these materials through the nose or mouth (huffing) occurs in teens and young adults. Axonal degeneration with sensory and motor impairment is seen, but focal conduction block associated with giant axonal swellings is also characteristic. The phenomenon is similar to the rare hereditary entity, giant axonal neuropathy, linked to a defect in the gigaxonin gene.

Ingested neurotoxins from various sea creatures harboring toxins can induce nerve dysfunction, mostly through sodium channel blockade and block in nerve conduction, mostly producing sensory neuropathy, cramps, diarrhea, and vomiting. Examples include ciguatera from reef fish exposed to a ciguatoxin-producing dinoflagellate, saxitoxin (paralytic shellfish poisoning), brevetoxin B (neurotoxic shellfish poisoning), and tetrodotoxin (puffer fish [fugu]). A number of insect venoms are also neurotoxic. Most cause neuromuscular junction blockade, but some, including tick paralysis and frog skin toxins, block sodium channels and peripheral nerve conduction.

Neuropathies Caused by Therapeutic Drugs

Many medications have been suspected of causing neuropathy, but relatively few have convincing clinical features, laboratory support, or reproduction in animal models. Different aspects of the problem are discussed in Chapters 109 and 133. Most of these neuropathies are dose related, presenting with predominantly sensory symptoms and signs or with a combination of sensory,

motor, and autonomic involvement. Most cause toxicity by targeting the axon or dorsal root ganglion neurons directly, but toxicity to Schwann cells and myelin occurs with some agents as well. Pathogenic mechanisms are agent specific and varied. Identification of a toxic effect is most simple when symptoms occur soon after drug exposure or a change in dosage. Most patients fall into this category. In contrast, it is problematic to diagnose a slowly progressive neuropathy starting many months or years on a chronic agent. For example, statin drugs provide a case in point and are discussed later. "Coasting" is a phenomenon in which neuropathy may continue to progress, usually for 2 to 3 weeks, despite drug discontinuation. Improvement after drug cessation helps support the toxic effect, but recovery may be delayed for many months or be incomplete when significant axonal degeneration occurs. Discussion of all of the numerous substances temporally linked to neuropathy is outside the scope of this chapter, and the interested reader should consult comprehensive reviews cited in the "Suggested Readings" section. Some of the more important and best established causes are discussed.

Chemotherapy is an area in which some toxicity is tolerable assuming the agent is efficacious. The most commonly used antineoplastic agents linked with neuropathy are *vincristine*, *cisplatin* (Platinol), *carboplatin*, *oxaliplatin*, and *taxoids* (paclitaxel, docetaxel). Vincristine causes a dose-dependent, symmetric, progressive sensorimotor distal neuropathy that begins in the legs and is associated with areflexia. The CMT type 1A patients are especially vulnerable, and treatment may unmask subclinical cases. In contrast, platin neuropathy is a purely sensory distal neuropathy with paresthesia, impaired vibration sense, and loss of ankle jerks, likely owing to toxicity and drug access to dorsal root ganglia but not α-motor neurons. The drug binds to and alters DNA and may trigger apoptosis if DNA repair fails. An additional acute, transient syndrome of cold-induced paresthesias, painful throat and jaw tightness, and occasionally focal weakness is associated with oxaliplatin infusion; peripheral nerve hyperexcitability has been demonstrated.

Paclitaxel (Taxol) is used to treat cancers of the breast, ovary, and lung. It causes a predominantly sensory neuropathy, but administration of a single high dose may affect motor and autonomic fibers as well. Disordered arrays of microtubules are induced. Neuropathy is also a prominent feature in chemotherapy with suramin (axonal or demyelinating), bortezomib (Velcade), misonidazole, ixabepilone, and thalidomide (sensory). Many chemoprotectant agents to blunt the neurotoxic effects have been studied; none are routinely used in humans, but some show promise. Use of numerous other therapeutic drugs may produce neuropathy, including colchicine (myoneuropathy), gold salts, isoniazid (without vitamin B_6), metronidazole, nitrofurantoin, and podophyllotoxin resin. Amiodarone (Cordarone) may cause a severe symmetric distal sensorimotor neuropathy, an autonomic or demyelinating neuropathy resembling CIDP. Phenytoin (Dilantin) may produce minor distal sensory impairment and areflexia but mostly after long-standing high dosage and is likely overdiagnosed. The major toxicity of some nucleoside analog antiretroviral medications (didanosine, zalcitabine, and stavudine) is peripheral neuropathy, which may be difficult to distinguish from HIV neuropathy. Others, such as azidothymidine, are not linked to neuropathy. A predominantly motor neuropathy has been related to disulfiram (Antabuse) and to dapsone. Statin use was associated with idiopathic neuropathy in a single large study, especially in those with definite neuropathy and longer term exposure. The methods of this study have been criticized, and the link remains controversial. Another large study in patients with diabetes mellitus found statin use protective against developing neuropathy.

Alcoholic Neuropathy

Peripheral neuropathy in alcohol abusers is well known, but the cause is still debated. A widely held belief is that the neuropathy of alcoholism is owing entirely to nutritional deficiency, particularly vitamin B_1 (thiamine). Koike and colleagues, however, provide the best support for a direct toxic effect of ethanol. Alcoholics with normal thiamine levels develop predominantly small-fiber sensory neuropathy, the most frequent clinical type. More subacute onset with motor involvement is also seen in alcoholics with thiamine deficiency and nondrinkers with primary thiamine deficiency. Symptoms of small-fiber neuropathy, such as burning and pain, are common in chronic alcohol drinkers. Later, loss of vibration sense, proprioception, and tendon reflexes may occur. Sensory ataxia may be problematic to separate from alcoholic cerebellar degeneration. Abstinence can lead to meaningful recovery; vitamin supplements alone are not clearly effective but advised.

Diabetic Neuropathy

Peripheral neuropathy occurs in approximately 50% of patients with diabetes mellitus, most commonly as a distal symmetric neuropathy. There are, however, several other distinct neuropathy syndromes that occur in patients with diabetes.

In one form, the symptoms and signs are transient; in the other, they progress steadily. The transient category includes acute painful neuropathies, mononeuropathies, and radiculopathies. The painful type starts abruptly with a disabling and continuous pain, often a burning sensation in a stocking distribution. Sometimes, the pain is localized to the thighs as a femoral neuropathy. The onset is often associated with weight loss. This disorder has been designated "diabetic neuropathic cachexia." The pain may last for months. Recovery from severe pain, however, is usually complete within 1 year, and the disorder does not necessarily progress to a conventional sensory polyneuropathy.

The progressive type comprises sensorimotor polyneuropathies with or without autonomic symptoms and signs. Although the actual cause of diabetic neuropathies is unknown, focal nerve involvement is considered to be immune mediated, and progressive symmetric polyneuropathy is probably owing to microvascular disease resulting from hyperglycemia. There may be as many causal factors as there are clinical pictures. There is evidence of oxidative damage and activation of protein kinase C β-activation in endothelial cells. However, it seems that hyperglycemic hypoxia is mainly responsible for the conduction changes seen in damaged diabetic nerves. Dysfunction of ion conductances, especially voltage-gated ion channels, could contribute to abnormalities in the generation and conduction of action potentials.

Impaired glucose tolerance is also associated with peripheral neuropathy. A 2-hour glucose tolerance test or a hemoglobulin A_{1c} can be used to screen for diabetes or impaired glucose tolerance in patients with neuropathy.

A syndrome recognized by a triad of pain; severe asymmetric muscle weakness; and wasting of the iliopsoas, quadriceps, and adductor muscles is named *diabetic amyotrophy* or *diabetic lumbosacral radiculoplexus neuropathy*. Onset is usually acute, but it may evolve

over weeks. It occurs primarily in older non–insulin-dependent diabetics and is often accompanied by severe weight loss and (diabetic neuropathic cachexia). Knee reflexes are absent, but there is little or no sensory loss. Although long described as involving the proximal leg muscles, this syndrome can also involve the arms and even respiratory system. The condition improves spontaneously but may last 1 to 3 years with incomplete recovery.

Generalized Polyneuropathies

The most common diabetic neuropathy is a diffuse distal symmetric and predominantly sensory neuropathy with or without autonomic manifestations. Balance may be impaired from proprioceptive loss. Distal limb weakness is usually minimal. The neuropathy develops slowly and is related to the duration of the diabetes, but not all patients are so afflicted. Once present, it does not resolve or significantly recover. Intensive glucose control limited complications, including peripheral neuropathy, in the diabetes control and complication trial with significant differences in nerve conduction values between intensive and standard glucose control groups LEVEL 1.[11] Pain and temperature sensation transmitted through the smallest fibers may be affected before the large-fiber modalities (vibration, light touch, position sense). Small-fiber function can be evaluated by determining perception thresholds for warming and cooling or increasingly by assessment of epidermal nerve fiber density from skin biopsy samples (Fig. 91.10). Many patients with diabetic neuropathy do not have pain but do have numb or anesthetic feet. Diabetic neuropathy is the major predictor of foot ulcers and amputations.

The prevalence of diabetic autonomic neuropathy (DAN) may be underestimated because nonspecific symptoms are undiagnosed or the condition may be asymptomatic. Symptoms appear insidiously after the onset of diabetes. The process progresses slowly and is usually irreversible. The DAN is an important prognostic indicator with a mortality rate in diabetics without other initial complications of 23% at 8 years compared to 3% at 8 years in diabetics without DAN and similar disease duration. Noninvasive autonomic screening batteries can be performed, and dedicated autonomic testing laboratories are becoming widely available (see Chapter 28).

FIGURE 91.10 Skin biopsy with staining for protein gene product 9.5, which shows a reduced number of nerve fibers crossing the epidermal-dermal border (magnification ×400).

Mild slowing of motor and sensory conduction is a common finding in diabetics, even among those without overt neuropathy. It is generally attributed to axonal degeneration with secondary demyelination. Therapeutic attempts, including continuous subcutaneous insulin infusion to correct hyperglycemia to prevent the diabetic complications, have been unsuccessful in most instances. Although combined pancreas and kidney transplantation may halt the progression of diabetic polyneuropathy, the long-term effect is still doubtful. Patients with pain may benefit from duloxetine or pregabalin, but side effects may preclude treatment in some.

Idiopathic Neuropathy

Patients with a peripheral neuropathy of undiagnosed cause may be later found to have an immune-mediated or hereditary neuropathy with more intensive evaluation. Even then, however, 10% to 35% of patients remain without an identified cause. Among those with painful sensory neuropathy involving the feet, this percentage is even higher. Although no cure is available for the neuropathy, treatment may include management of pain, physical therapy, and counseling related to prognosis. When there is no identifiable cause of a symmetric predominantly sensory neuropathy, after a thorough evaluation, the neuropathy rarely progresses to loss of ambulation or disability. Persistent pain is a frequent problem. Care must be taken to conduct an adequate search for treatable underlying disorders.

Inherited Peripheral Neuropathies 92

Chiara Pisciotta and Michael E. Shy

KEY POINTS

1. Inherited neuropathies, or Charcot-Marie-Tooth (CMT) disease, are genetically heterogeneous conditions, but the type of CMT can be determined by distinguishing characteristics.
2. The prevalence of the various mutations, inheritance pattern, nerve conductions, and age of onset help in deciding what genetic testing should be ordered.
3. Next-generation sequencing technology has identified a growing number of candidate gene mutations with complex and sometimes uncertain phenotypic correlations.
4. CMT is a rapidly evolving field where better understanding of pathophysiology is paving the way to develop potentially effective treatments.

INTRODUCTION

Inherited neuropathies, collectively known as *Charcot-Marie-Tooth* (CMT) *disease*, are a group of genetically and phenotypically heterogeneous peripheral neuropathies associated with mutations or copy number variations in approximately 100 different genes, many uncovered recently thanks to next-generation sequencing technology. Named after the three neurologists who first described the condition in 1886, CMT is the most common inherited neuromuscular disease. Hereditary neuropathies are classified as CMT (or hereditary motor sensory neuropathy) if motor and sensory system are both affected; as hereditary sensory/autonomic neuropathy (HSN or HSAN), if sensory and/or autonomic dysfunction prevail; and as distal hereditary motor neuropathy (dHMN), if motor deficit is predominant. These three disorders represent a continuum and are often collectively termed *Charcot-Marie-Tooth and related disorders*.

According to electrophysiologic criteria, CMT neuropathies are classified into two main subgroups: the demyelinating type CMT1 with reduced nerve conduction velocities (NCVs) in the arms of less than 38 m/s, and the axonal type CMT2 with primarily axonal loss characterized by normal NCV and decreased amplitude of motor (CMAP) and sensory nerve action potentials (SNAP). An intermediate CMT form with median motor NCV between 25 and 45 m/s has been defined.

Further subdivision of CMT are based on the inheritance pattern and the molecular genetic defects. Inheritance in CMT can be autosomal dominant (AD), autosomal recessive (AR), or X-linked. By convention, AR demyelinating forms of CMT1 are referred to as *CMT4* and AR axonal forms are also known as *AR-CMT2*. X-linked CMT is usually referred to as *CMTX*.

The term *Dejerine-Sottas neuropathy* (DSN) is currently used primarily to denote severe early-onset clinical phenotypes regardless of the inheritance pattern. The classification of CMT has been divided further into subtypes, identified by letters, as defined by the mutated gene.

Gene discoveries within the past two decades have challenged the simplistic classification of CMT, as for example, we have reached all 26 alphabet letters for CMT2. A modification of the current nomenclature of CMT and related disorders, which takes into account the causative gene defect, inheritance pattern, and primary pathologic phenotype (axonal, demyelinating, or intermediate), has been recently proposed but needs further discussion and widespread agreement.

EPIDEMIOLOGY

The prevalence of CMT is about 1 in 2,500 people, with a global distribution and no ethnic predisposition. Epidemiologic studies are still scarce, and knowledge of CMT frequency in different parts of the world remains extremely limited. The European prevalence rate is believed to be 10 to 28/100,000.

CMT1A, associated with a 17p11.2 duplication in the region containing the peripheral myelin protein 22 gene (*PMP22*), is the most common form of CMT and accounts for about 60% of patients with genetic diagnosis and about half of all patients with CMT. Mutations in the gap junction beta 1 (*GJB1*) gene cause CMT1X, which comprises approximately 10% to 20% of CMT cases, and CMT1B associated with mutations in the myelin protein zero (*MPZ*) gene accounts for about 7%. Patients with CMT2 are about 15% to 20% of all cases, and CMT2A (*mitofusin 2* mutation) is the most frequent form comprising roughly 20% of patients with CMT2. Fifty percent of CMT2 genes have yet to be identified. The prevalence of hereditary neuropathy with liability to pressure palsies (HNPP) is about 3% of patients with genetic diagnosis.

Many studies find that about 90% of patients with genetically confirmed CMT diagnosis have a mutation in one of these four genes: *PMP22* (duplication), *GJB1*, *MPZ*, and either *MFN2* or *GDAP1*, according to the geographic area. The former is more frequent in North America and Northern Europe, the latter in the Mediterranean area.

PATHOBIOLOGY

A common feature of most genes mutated in CMT is the role they play in maintaining the structure or function of cellular components of the peripheral nervous system, myelinating Schwann cells, and the axons they ensheath. Schwann cells and axons interact at multiple points along the peripheral nerve, including the adaxonal (opposing the axon) membrane, paranodal myelin loops, microvilli, and juxtaparanodal basal lamina. These interactions are mutually beneficial, providing trophic support

to the axon and myelinating cues to the Schwann cell. An example of this important interaction is the occurrence of secondary axonal degeneration in all forms of demyelinating CMT. Indeed, although the primary metabolic or structural defect often affects either the myelin or the axon, axonal degeneration represents the final common pathway in both forms of peripheral neuropathies. In demyelinating neuropathies, the secondary axonal degeneration presumably occurs because of inadequate Schwann cell support of the axon. In these neuropathies, secondary axonal degeneration may contribute more to clinical impairment than the primary demyelination. Impaired interactions between axons and mutant Schwann cells seem to be the common process linking all forms of demyelinating CMT. Most cases of CMT1 are caused by mutations in myelin-specific genes including *PMP22* (CMT1A), *MPZ* (CMT1B), and *GJB1* (CMTX1) or other genes associated with Schwann cell function, including those that exert transcriptional control of myelination and intracellular trafficking. At a pathologic level, dysmyelination, demyelination, remyelination, and axonal loss are characteristic features of the various demyelinating forms of CMT1. In DSN, myelin may never have formed normally, which is referred to as *dysmyelination*. In CMT1, onion bulbs of concentric Schwann cell lamellae are usually present on nerve biopsies, with loss of both small- and large-diameter myelinated fibers and a decrease in the number of myelinated axons. Focal, sausage-like thickenings of the myelin sheath (tomacula) are characteristic of HNPP but may also be found in other forms of CMT1, particularly CMT1B. In CMT1, disability typically correlates better with secondary axonal degeneration than with demyelination itself, again demonstrating the importance of Schwann cell–axonal interactions in demyelinating disease (**Fig. 92.1**).

Several recent studies have demonstrated a susceptibility of Schwann cells to mutations yielding misfolded proteins, as seen in certain *PMP22* and *MPZ* point mutations. Misfolded proteins may accumulate in the endoplasmic reticulum (ER) of Schwann cells inducing an unfolded protein response (UPR), a series of cellular events that help the ER to cope with the increased metabolic demand caused by retention of the misfolded protein. This, in turn, causes downregulation of the myelination program genes and dedifferentiation of Schwann cells, a toxic gain of function that worsens with the demyelination and is potentially amenable to therapeutic intervention.

Spinal motor neurons and dorsal root ganglion sensory neurons that are affected in CMT have particular challenges in maintaining homeostasis because their axons extend up to 1 m distal from the cell body. Because the majority of neuronal proteins are synthesized in the cell body, intensive transport of proteins must occur between the soma and the axonal extremity via anterograde transport. Additionally, signals from the periphery containing toxic or prosurvival factors, as well as damaged proteins, return to the cell body via retrograde transport. Indeed, axonal trafficking is emerging as a common theme of various seemingly diverse genes that are associated with CMT type 2. Mutations in genes associated with axonal structure and function result in CMT2. Some examples include mutations in proteins of the neuronal cytoskeleton (neurofilament light chain-NEFL, CMT2E), proteins associated with axonal mitochondrial dynamics (mitofusin 2-MFN2, CMT2A, and ganglioside-induced differentiation protein 1-GDAP1, CMT2K), and protein associated with regulation of membrane and intracellular trafficking (eg, Ras-associated protein RAB7, CMT2B). The pathologic hallmark of CMT2 is axonal degeneration with loss of all types of nerve fibers in the absence of onion bulb formation.

The advanced discovery of new causative genes unraveled previously unrecognized and unexpected neuropathy mechanism including nuclear envelope structure, mitochondrial dynamics, protein biosynthesis, Ca2+ homeostasis, phosphoinositide metabolism, sugar synthesis metabolic pathway, and transcriptional regulation.

FIGURE 92.1 Pathologic findings in demyelinating Charcot-Marie-Tooth disease. **A:** Cross-section of a sural nerve biopsy of a patient with demyelinating Charcot-Marie-Tooth showing numerous demyelinated axons *(arrows)* and occasional classical onion bulbs *(asterisk)*. Thionine and acridine orange stain. Bar = 10 μm. **B:** Electron micrograph showing a demyelinated axon *(asterisk)* surrounded by some excess basal lamina. The Schwann cells associated with small, unmyelinated axons are abnormally long and attenuated *(arrows)*. Bar = 1 μm. (From Saporta MA, Shy ME. Inherited peripheral neuropathies. *Neurol Clin*. 2013;31:597-619.)

CLINICAL PRESENTATION

Despite phenotypic variability, there are characteristic clinical patterns for many types of CMT. The "classical" CMT phenotype consists of normal early milestones such as beginning to walk by approximately a year of age. This is followed by gradually progressing weakness and sensory loss during the first two decades of life. The classic phenotype typically features a steppage gait, pes cavus, sensory loss in a stocking or glove distribution, inverted champagne bottle legs, and atrophy in the hands (Fig. 92.2). Although both motor and sensory nerves are usually affected, the more prominent phenotypic characteristic is related to motor difficulty in most cases. Physical examination shows decreased or absent deep tendon reflexes often diffusely but always involving the Achilles tendon. Findings are usually symmetric. Pronounced asymmetries in symptoms suggest HNPP if they are episodic. Otherwise, they are more consistent with acquired disorders. Patients with classical CMT almost always have impaired proprioception with balance difficulty. Affected children are usually slow runners and have difficulty with activities that require balance (eg, skating, walking along a log across a stream). Ankle-foot orthotics is frequently required by the third decade.

FIGURE 92.2 **A:** Wasting of distal muscles in lower limbs leading to inverted champagne bottle legs. **B:** Example of wasting of intrinsic muscles of the hands. **C:** Pes cavus with hammer toes.

Fine movements of the hands for activities such as turning a key or using buttons and zippers may be impaired, but the hands are rarely as affected as the feet. Deep and superficial muscles that are innervated by the peroneal nerve, such as the tibialis anterior and peroneus brevis and longus muscles, often cause more symptoms than do the plantar flexion muscles innervated by the tibial nerve, such as the gastrocnemius. As a result, tripping and spraining one's ankle are frequent symptoms. Most patients remain ambulatory throughout life and have a normal life span.

However, CMT may be clinically, as well as genetically heterogeneous, with variability in the age of onset, speed of progression, and electrophysiologic findings. Onset may differ depending on the genetic subtype, including early-onset, infantile forms with delayed milestones (historically designated DSN), and late-onset adult forms. Symptoms are usually slowly progressive, especially for the classic and late-onset phenotype but can be severe, particularly in early-onset forms (Table 92.1).

DIAGNOSIS

Peripheral neuropathy is one of the most common reasons for referrals to neurologic clinics. The first step is to determine whether the patient has a genetic neuropathy. Where there is an affected parent, either an AD or X-linked (if there is no definite male-to-male transmission) inheritance is likely. If there are multiple affected siblings, no parents affected, and/or consanguineous parents, then AR inheritance is likely. However, recognizing CMT can be challenging particularly when there is no family history or if families are small. Factors pointing to an inherited neuropathy in such circumstances include presentations in childhood, slow progression, the presence of foot deformities, and the lack of positive sensory symptoms (dysesthesias, paresthesias) in the presence of clear sensory signs. Patients may have undergone foot surgery in childhood or reported difficulties with sports at school.

Genetic Testing

Genetic testing is the "gold standard" for the diagnosis of inherited neuropathies. However, it is a challenge to keep the costs reasonable particularly because there are so many known genetic causes. Although there are many genes associated with CMT, in North America, mutations in only four genes (*PMP22* duplication/deletion, *GJB1*, *MPZ*, and *MFN2*) account for over 90% of CMT cases. These data justify a stepwise diagnostic algorithm based on phenotype, inheritance pattern, NCVs, frequency of subtypes, and ethnicity. Although this approach is reasonably successful, with over 60% of patients with CMT achieving a genetic diagnosis, it is no longer the most efficient, rapid, or cost-effective method of achieving a molecular diagnosis, especially for CMT2, dHMN, and HSAN. In fact, diagnostic approaches are shifting to incorporate rapidly developing next-generation sequencing panels because the cost of these drops below that of serial candidate gene screening. Therefore, a practical approach is to consider commercial panels that contain the common CMT genes (*PMP22*, *GJB1*, *MPZ*, *MFN2*, *GDAP1*, *HSPB1*, *HSPB8*), taking into account the clinical data. Current multigene panel testing is increasingly the first-line approach for many patients with whole exome sequencing as back up, although initial targeted testing for *PMP22* duplication in patients with demyelinating CMT is appropriate. Most mutations that change the amino acid sequence in *PMP22*, *MPZ*, and *GJB1* cause disease, but polymorphisms are frequent in

TABLE 92.1 Specific Phenotypes of Charcot-Marie-Tooth (CMT)

Type	Specific Phenotype
CMT1	
CMT1A	Classic CMT phenotype with disease onset in the first two decades of life. Patients complain of walking difficulties, distal weakness associated with wasting, sensory loss, and foot deformities. Slow progression and AFOs often required. MNCVs are uniformly slow (mean range 17-21 m/s).
CMT1B	Associated with distinct phenotypes: late mild phenotype, adult-onset, and intermediate MNCVs; DSN with early infantile onset, severe phenotype, delayed walking, and MNCV <10 m/s; classic CMT phenotype (see CMT1A)
CMT1C	CMT1 (frequently resemble those with CMT1A)
CMT1D	Usually presents with DSN
CMT1E	Distinct phenotypes depending on the location and amino acid change: DSN with early onset, delay in walking, severe phenotype (deafness may also be present), very slow MNCVs; CMT1 with later onset and milder phenotype; HNPP
CMT1F	"Demyelinating" form of CMT2E with earlier onset (infancy or childhood), more severe phenotype (delayed motor milestones), and slower MNCVs
HNPP	Recurrent episodic painless mononeuropathies, typically at entrapment sites, in response to nerve injury from pressure or stretching; superimposed, length-dependent, sensory-predominant neuropathy of large fibers
X-Linked CMT	
CMT1X	Males have a more severe phenotype than females. MNCVs in the intermediate range (male MNCVs < female MNCVs). Nerve conduction can be patchy with temporal dispersion and conduction blocks, especially in females.
CMT2	
CMT2A	Usually severe phenotype with onset in infancy or early childhood, progressive course, and predominant motor involvement with many patients requiring a wheelchair to ambulate by the age of 20 years. Rarely, later onset and milder phenotype. Additional clinical features may be present as optic atrophy or pyramidal signs.
CMT2B	Predominant sensory involvement with ulcerations, infections, and sometimes amputations. Patients usually have in addition the typical motor symptoms of CMT. Autonomic dysfunctions can be also observed.
CMT2C	Predominant motor involvement, vocal cord paralysis (hoarseness and stridor), and respiratory dysfunction. Other distinctive clinical features may include bone deformities such as scoliosis, short stature, and/or scapular winging. The age of onset is often in the first decade of life.
CMT2D	It usually presents in the second decade with more pronounced weakness and wasting of the distal upper extremities compared to the lower extremities. Sensory findings are usually mild and may even be absent. In this situation, the disorder has been classified as dHMN type V.
CMT2E	The age of onset ranges from infancy and childhood typically with severe impairment to adulthood with mild impairment. Weakness and wasting start in the legs with all sensory modalities reported to be affected. MNCVs can be normal, intermediate, or slow (CMT1F).
CMT2F	Most patients have a dHMN phenotype (dHMN type IIB). Typically, this is a motor distal length-dependent neuropathy with slow progression proximally of symptoms. Sensory findings may be present, especially later in the disease course. The age of onset is typically late adolescence to early adulthood
CMT2L	CMT2 or dHMN-IIA if sensory involvement is not present (see CMT2F)
CMT2K	Typically results in a much milder phenotype than the recessive form (CMT4A) with no vocal cord involvement and onset ranging from adolescence to adulthood
CMT4/AR-CMT2	
CMT4A	Infantile-onset, severe progressive neuropathy with a variable vocal cord involvement and diaphragm paralysis
CMT4B1	Infantile onset with severe phenotype (both proximal and distal) cranial nerve involvement, especially facial weakness. Wheelchair dependent by adulthood.
CMT4C	The phenotype can be severe with early and severe scoliosis. The onset is slightly later than other AR-CMT.
CMT4F	Severe early-onset neuropathy with prominent sensory involvement and ataxia
CMT4J	Onset in early childhood with a severe motor phenotype, sometimes asymmetric. Rapid progression to a wheelchair has been described in adulthood.
AR-CMT2A	Severe axonal neuropathy with proximal involvement and rapid progression. Cardiomyopathy can be an associated feature. Onset usually in the second decade of life.

Abbreviations: AFOs, ankle-foot orthotics; AR, autosomal recessive; CMT1, autosomal dominant demyelinating Charcot-Marie-Tooth; CMT2, autosomal dominant axonal Charcot-Marie-Tooth; CMT4, autosomal recessive demyelinating Charcot-Marie-Tooth; dHMN, distal hereditary motor neuropathy; DSN, Dejerine-Sottas neuropathy; HNPP, hereditary neuropathy with liability to pressure palsies; MNCV, motor nerve conduction velocity.

most other genes and interpretation of disease-causing mutations are a challenge. We suggest following the recommendations of the American College of Human Genetics (see "Suggested Readings" section) in determining whether a variant is disease causing, which includes whether the variant segregates with disease, is present in the population, is conserved throughout evolution, and is predicted to be damaging.

The authors also believe it is still reasonable to provide some information about how to pursue genetic testing that must take into account the frequency of the subtypes, the phenotype and electrophysiologic characteristics, and the inheritance pattern. This can be quite challenging because the same gene can be involved in demyelinating, axonal, or intermediate forms and can display AD or AR inheritance depending on the nature and position of the mutation.

Age of Onset and Progression

Three different categories can be identified. Patients with a classical phenotype, who begin walking on time and develop weakness or sensory loss during the first two decades of life, belong to the first group. Impairment slowly increases and patients rarely require ambulation aids beyond ankle-foot orthotics. The large majority of patients with CMT1A and males with CMT1X fall into this category.

The second group is the early-onset phenotypes in which patients do not begin walking until they are at least 15 months of age. These patients are often severely affected and are likely to require above-the-knee bracing, walkers, or wheelchairs for ambulation by 20 years of age. The genetic spectrum of early-onset CMT is very heterogeneous, including both dominant and recessive forms. The majority of these represent demyelinating phenotypes with very slow motor nerve conduction velocities (MNCVs) and the most common are CMT1A, CMT1B, and CMT1E for the dominant forms and CMT4A, CMT4C, and CMT4F for the recessive ones. In addition to the demyelinating phenotypes, severe early-onset axonal neuropathies can be due to *MFN2* (CMT2A) or *GDAP1* (AR-CMT2K) mutations. Patients with CMT2A are frequently, although not always severely affected in infancy and childhood and present with a predominant motor neuropathy.

The third phenotype is defined as adult onset, in which patients do not develop symptoms of CMT until adulthood, often not until approximately 40 years of age. A large group of patients with axonal CMT and patients with a later onset CMT1B fall into this group.

Associated Symptoms and Signs

The recognition of additional symptoms and signs can lead to a better definition of the type of CMT. A recurrent nerve palsy history is typical of HNPP, which presents with transient focal motor and/or sensory deficits in the distribution of individual nerves or plexuses, usually precipitated by pressure. A split hand syndrome (the abductor pollicis brevis being more wasted and weaker than the first dorsal interosseous) is a distinctive sign of CMT1X, especially males. Transient CNS dysfunction and stroke-like episodes characterized by dysarthria, episodic weakness, and ataxia are also rarely reported by young males with CMT1X. Optic atrophy and pyramidal signs are occasionally observed in patients with *MFN2* mutations. Vocal cord paralysis is frequent in CMT2C, caused by mutations in *TRPV4* (transient receptor potential cation channel subfamily V member 4) gene as well as by mutations in MFN2 and several other genes. Tonic pupils can be an additional clinical feature of some axonal late-onset forms due to *MPZ* mutations (eg, Thr124Met). Amputations and skin ulcers are the main feature of CMT2B and other autonomic symptoms, as light-headedness or hypo-/hyperhidrosis, can be reported. Mutations in *SH3TC2* (SH3 domain and tetratricopeptide repeat domain 2) gene, causing CMT4C, are a frequent cause of significant scoliosis.

Neurophysiologic Pattern

CMT1 are characterized by MNCVs at upper limbs below 38 m/s with widespread uniform slowing of conduction velocities, as opposed to the multifocal segmental slowing found in demyelinating acquired neuropathies in which temporal dispersion and conduction blocks are frequently seen. Exceptions to this rule are patients with HNPP and patients with mutations in *FIG4* (CMT4J). In these cases, focal demyelination with temporal dispersion or conduction block can be seen. In CMT1A, MNCVs are uniformly slow in all nerves with a mean range of 17 to 21 m/s. Very slow MNCVs (<10 m/s) are suggestive of early-onset CM1B, *PMP22* point mutations, or demyelinating recessive phenotypes (CMT4).

Preserved or mildly slowed MNCV (mostly >45 m/s at upper limbs) and reduced compound muscle sction potential (CMAP) amplitude are in keeping with CMT2. Especially for severe phenotypes, in which CMAP and SNAP are unobtainable distally, it is recommended to perform nerve conductions on proximal nerves for a proper diagnostic workup to fully investigate the possibility of a severe demyelinating rather than an axonal pathology. Sensory nerve conduction evaluation is required to differentiate CMT2 from dHMN, and it should be performed especially at lower limbs because SNAP amplitude could be normal at upper limbs in mild phenotypes. Some forms of dHMN can have a minimal sensory impairment, and in these cases, the discrepancy between CMAP and SNAP amplitude reduction should be taken into account for the differential diagnosis.

"Intermediate" MNCV, in the range of 25 to 45 m/s, is consistent with I-CMT. MNCVs are not uniformly slow and can differ among different nerves in the same individuals or among family members. Therefore, although a single nerve can be sufficient to make a diagnosis of CMT1, multiple nerve evaluation must be performed especially in these cases. Temporal dispersion and conduction blocks can also be present. The most common intermediate forms of CMT are due to *MPZ* and *GJB1* mutations. Focal slowing at typical sites of compression (median nerve at wrist, ulnar nerve at elbow, and peroneal nerve at fibular head) and a superimposed, diffuse, sensory neuropathy is suggestive of HNPP.

Inheritance Pattern

The AD transmission is the most common pattern of inheritance in CMT with a vertical transmission from a generation to another. If there is no male-to-male transmission, X-linked inheritance should be taken into account, whereas in case of consanguinity, AR inheritance is likely. However, many patients present with no clear family history and these cases should be considered as sporadic cases due to de novo mutation, reduced penetrance/intrafamilial variability, or proband of an AR inheritance. So, the absence of a family history of neuropathy should not dissuade clinicians from considering an underlying genetic cause.

At-Risk Populations

It is important to be aware of the specific mutation frequencies occurring in certain populations because some genetic mutations have been reported in specific race-ethnic groups. In northern Europe and the United States, AD inheritance is much more common than AR, which should be considered for those patients coming from countries where consanguinity is more frequent, such as Mediterranean and Middle Eastern populations.

MANAGEMENT

Despite the great improvement in our biologic understanding of inherited neuropathies, derived mostly from developments in molecular biology and transgenic animal models in the last 25 years, there is still no treatment available for any type of CMT. Physical therapy, occupational therapy, and a few orthopedic procedures are still the cornerstone of CMT treatment. A detailed family history and often examination of family members are required for prognosis and genetic counseling.

A dedicated, multidisciplinary rehabilitation team can significantly contribute to the management of patients with CMT and improve functionality and quality of life. Physical therapy strategies to maintain muscle strength and tone, prevent muscle contractures, and improve balance are a common need for most patients with CMT. Orthotics also are an important component of treating these patients, providing support and improving balance for ambulation. Occupational therapy focused on developing tools and strategies to help patients with activities of daily living will benefit patients with CMT, especially those with hand weakness. Tendon lengthening and tendon transfers can benefit a subset of CMT patients with muscle contractures and tendon shortening and patients with significant weakness in functionally relevant muscles, respectively; however, the optimal timing of such procedures is still controversial. Foot surgery is sometimes offered to correct inverted feet, pes cavus, and hammertoes. This surgical intervention may improve walking, alleviate pain over pressure points, and prevent plantar ulcers. However, foot surgery is generally unnecessary and does not improve weakness and sensory loss (**Table 92.2**).

However, many promising compounds are being tested in cellular and animal models and may reach the phase of assessing tolerability and effectiveness in clinical trials.

TABLE 92.2 Treatments and Aims

Physical therapy	To maintain muscle strength and tone, prevent muscle contractures, and improve balance
Orthotics	To provide support and improve balance for ambulation
Occupational therapy	To provide tools and strategies for activities of daily living, especially for patients with hand weakness
Tendon lengthening	For patients with muscle contractures and tendon shortening
Tendon transfers	For patients with significant weakness in functionally relevant muscles
Foot surgery	To correct inverted feet, pes cavus, and hammer toes. It may improve walking and prevent plantar ulcers.

Gene Therapy

Gene therapy is becoming reality for many previously incurable neuromuscular disorders. Reducing the expression of PMP22 in Schwann cells (hence treating the overexpression of PMP22) is a biologic strategy already tested to treat CMT1A. Recently, Zhao et al treated two rodent models of CMT1A with PMP22-targeting antisense oligonucleotides and showed a 35% reduction in PMP22 messenger RNA (mRNA). This reduction was not only adequate in slowing disease progression but also improved the CMT1A-associated phenotypes in both models, offering evidence that another previously untreatable neuromuscular disease is becoming a treatable disorder.

Regulation of a mutant allele by an allele-specific small interfering RNA can represent a therapeutic approach as well. Lee at al designed allele-specific small interfering RNAs for a mouse model harboring a missense mutation (L16P) in *PMP22*, a model of CMT1E. The treatment reduced L16P-*PMP22* mRNA in Schwann cells and improved the mouse phenotype.

A gene therapy approach has been successfully performed by Kleopa and colleagues using intrathecal injection of *GJB1*, with both lentivirus and AAV9 vectors and the myelin-specific *MPZ* promoter, in *GJB1*-knocked-out mice lacking Cx32 expression. Gene delivery appeared to result in stable Cx32 expression in Schwann cells and peripheral nerves and clinical improvement. The same approach was successfully used by the group in the *SH3TC2*/mouse model of CMT4C.

Normalization of Gene Dosage

As previously mentioned, reducing the expression of PMP22 in Schwann cells is a strategy to treat CMT1A. High-dose ascorbic acid (vitamin C) was shown to decrease PMP22 levels and symptoms in mice with CMT1A, so that they were able to stay on a rotating rod longer, cross a beam more rapidly, and grip for longer than untreated mice. Several studies have been performed in humans with CMT1A, testing different doses of vitamin C (1-4 g/d) for up to 2 years. Unfortunately, all studies failed to meet their primary outcome measures and did not show a significant effect on phenotype.

A phase III trial in CMT1A is in progress employing PXT3003, a mixture of low-dose sorbitol, naltrexone, and baclofen, after encouraging results in the animal model and a phase II trial.

Steroid hormones are epigenetic regulators of gene expression, and progesterone can stimulate PMP22 expression in cultured Schwann cells. Progesterone antagonists have been shown to decrease PMP22 expression in a rat model of CMT1A, improving their phenotype (specifically, the axonal loss seen during disease progression). Unfortunately, onapristone, the compound shown to have therapeutic effects in this study, do not have an appropriate safety profile to be administered in humans. Efforts to develop bioequivalent compounds with a better safety profile are ongoing.

Neurotrophic Support

The growth factor neurotrophin 3 promotes nerve regeneration after injury and the survival of Schwann cells. Accordingly, injection of recombinant neurotrophin 3 improved regeneration and remyelination in animal models. A pilot study in eight patients with CMT1A resulted in an increase in myelinated fiber density, a reduction in the neurologic impairment score, and improved sensory

modalities as compared with placebo controls, calling for a larger randomized controlled trial. An additional study provided preclinical data demonstrating efficacy of adeno-associated virus–mediated neurotrophin 3 gene therapy in a mouse model of CMT1A.

Neuregulin1-III (Nrg1-III) activity determines myelin thickness and is regulated by the secretases β-site APP cleaving enzymes 1 (BACE1) and TNFα-converting enzyme (TACE). It is reasonable that modulating Nrg1-III activity may constitute a general therapeutic strategy to treat CMT that are characterized by de/dysmyelination. Recently, genetic overexpression of Nrg1-III has been shown to ameliorate the neurophysiologic and morphologic parameters in a mouse model of CMT1B and stimulating Nrg1-III signaling by pharmacologic suppression of the Nrg1-III inhibitor TACE also ameliorated the neuropathy. Conversely, increasing TACE activity with the commercially available niacin (Niaspan) is of benefit in different models of hypermyelination neuropathies, as CMT4B.

Reduction of Neurotoxic Aggregates/ Misfolded Proteins

Recent studies have demonstrated the role of ER accumulation of misfolded proteins and UPR activation in the pathogenesis of several animal models of CMT associated with point mutations in myelin-related genes, including *PMP22* and *MPZ*. Furthermore, treatment with an agent that relieves ER stress (curcumin) improved the phenotype of both models. Therefore, compounds that either relieve ER stress or reduced UPR activation are promising therapeutic strategies to treat patients with mutations that cause misfolded proteins to accumulate in the ER of Schwann cells. For example, Sephin1, which attenuates the inositol-requiring enzyme 1 (IRE1) branch of the UPR, may be an effective approach to improve myelination in those cases of CMT1B in which the UPR is active.

Targeting Transport Defects

An important therapeutic target is axonal transport, which likely plays a key role in several CMT subtypes, but treatment strategies for axonal forms of CMT have not been as easily identified as for demyelinating forms. Histone deacetylase-6 inhibitors have been shown to correct axonal transport defects in a mouse model of CMT2F associated with point mutations in the *HSPB1* gene, rescuing the axonal loss and clinical phenotype of these mice. It remains to be shown whether this same strategy could be useful in other forms of axonal CMT because correcting axonal transport defects may be a common treatment option for most of these CMT types.

Cellular Reprogramming and High-Throughput Therapeutic Screening

Two new technologies recently developed hold enormous potential in the search for compounds to treat CMT: cellular reprogramming and high-throughput therapeutic screening. Cellular reprogramming is a technique that allows the generation of specific cell types (including stem cell–like cells, neurons, and glia) by genetically modifying readily available somatic cells such as fibroblasts or lymphocytes. Using this technology, researchers are able to generate unlimited supplies of patient-specific cell lines for use in mechanistic studies and drug development. These patient-specific cell lines will be particularly useful when combined with high-throughput screening of drug libraries containing thousands of compounds. In these highly automated platforms, the process of identifying compounds capable of correcting certain disease-related cell phenotypes is streamlined, allowing for a faster target selection of compounds to be tested in phase 1 animal studies. The use of patient-derived human cells offer the theoretical advantage of a more translational platform, which could facilitate the process of moving from phase 1 studies to human clinical trials. Whether this is actually true remains to be proven.

OUTCOME

Phenotypic variability occurs within given phenotypes, and natural history studies of most forms of CMT are lacking. Nevertheless, most patients remain ambulatory throughout life and life span is not typically shortened. Some patients do not develop symptoms until adult years.

The attempt in searching for genetic modifiers that may account for the phenotypic variability is an emerging research field. CMT1A is a valuable target for modifier gene studies because it is by far the most common form of CMT, and despite its genetic homogeneity, patients present with considerable clinical phenotypic variability. Recently, signal-induced proliferation-associated 1 like 2 (*SIPA1L2*) gene has been found as a potential genetic modifier of CMT1A phenotypic expressions and offering a new pathway to therapeutic interventions.

As novel treatments are approaching, a parallel research line is aimed at preparing clinical trials and finding responsive outcome measures to detect treatment efficacy in a reasonable time period and with feasible sample sizes. With neuropathies that progress slowly over many years, this can be challenging. To this end, a validated scoring system (CMT neuropathy score) based on symptoms, signs, and neurophysiologic data has been developed for adults with excellent inter- and intraobserver correlations and which can detect changes over 1 year. A more sensitive CMT pediatric score (CMTPedS) exists for those patients between the ages of 3 and 21 years, which takes into account growth-related changes and should prove useful in future clinical trials. Sequential yearly magnetic resonance imaging of limb muscles looking at progressive replacement of muscle with fatty tissue proved to be a valuable outcome measurement in a cohort of CMT1A and HSAN1 patients. Nerve and muscle ultrasound echography and magnetic resonance neurography are providing accurate images in different peripheral neuropathies including CMT and might become useful also for follow-up studies. Meaningful biomarkers are actively searched for in skin biopsies, blood, and cerebrospinal spinal fluid. For this reason, skin biopsies have been increasingly used in the diagnostics and research of hereditary peripheral neuropathies by both morphologic and morphometric analysis of cutaneous nerve fibers. Moreover, changes of the level of certain myelin proteins and respective mRNA can be quantified. Indeed, Svaren et al recently developed a novel method for precise evaluation of *PMP22* levels in skin biopsies in CMT1A, and the analysis showed reproducible evaluation in CMT1A versus controls skin biopsies, particularly after normalization to Schwann cell-specific genes. Lastly, a proteomics-based approach performed on lymphoblasts from CMT2 patients resulted in the identification of profilin 2 (PFN2) and guanidinoacetate methyltransferase (GAMT) as commonly downregulated proteins in different genotypes, unveiling two molecular determinant as potential biomarkers in CMT2.

93 Myasthenia Gravis and Other Disorders of the Neuromuscular Junction

Christina M. Ulane

KEY POINTS

1. Disorders of the neuromuscular junction cause fluctuating weakness, without sensory symptoms or findings.
2. Myasthenia gravis is the prototypical autoimmune postsynaptic neuromuscular junction disorder with autoantibodies most commonly against the acetylcholine receptor (also against other postsynaptic membrane proteins).
3. Treatment of myasthenia gravis is highly individualized and includes symptomatic treatments, immediate/acute treatment for exacerbations, and long-term immunomodulatory treatment to reduce disease activity.
4. Numerous new and exciting treatment options are now available for myasthenia gravis.
5. Lambert-Eaton myasthenic syndrome and botulism are prototypical presynaptic neuromuscular junction disorders, which are rarer but important entities to recognize.
6. Much progress has been made in understanding the pathobiology of congenital myasthenic syndromes and the underlying genetic causes, and specific symptomatic treatment is available for certain syndromes.

INTRODUCTION

Pathology at the neuromuscular junction (NMJ) can occur at the presynaptic or postsynaptic membrane. Autoimmune disorders, hereditary diseases, and toxins are the main types of disease which affect the NMJ.

MYASTHENIA GRAVIS

Myasthenia gravis (MG) is caused by a defect of neuromuscular transmission owing to antibody-mediated attack on nicotinic acetylcholine receptors (AChR) or other functionally related proteins at the postsynaptic membrane of the NMJ, such as muscle-specific tyrosine kinase (MuSK), agrin, and lipoprotein receptor–related protein 4 (LRP4). It is characterized by fluctuating weakness restricted to the skeletal muscles, which can be focal or generalized and almost always includes eye muscles. The weakness in the limbs is symmetrical and typically more proximal than distal. Respiratory and bulbar muscles may also become involved. There are several different subgroups of MG, which have treatment and prognostic implications (Table 93.1).

Epidemiology

The prevalence of MG is 150 to 250 cases per million, with an incidence of 8 to 10 cases per million persons. These numbers have increased with greater awareness and improved diagnosis. MG is equally present in men and women older than the age of 40 years; however, it is 3 times more common in women than men younger than 40 years of age. MuSK myasthenia is also more common in women.

Systemic autoimmune disorders are found with greater incidence in patients with MG. Thyroid disorders are present in up to 15% of patients with MG. Other autoimmune disorders with increased incidence in patients with MG include rheumatoid arthritis and systemic lupus erythematosus (SLE).

Familial cases are rare; single members of pairs of fraternal twins and several sets of identical twins have been affected. Young women with MG tend to have human leukocyte antigen (HLA)-B8, HLA-DR3, and HLA-DQB1*0102 haplotypes; in young Japanese women, HLA-A12 is prominent. These observations imply the presence of a linked immune response gene that encodes a protein involved in the autoimmune response. First-degree relatives show an increased incidence of other autoimmune diseases (SLE, rheumatoid arthritis, thyroid disease) and HLA-B8 haplotype.

Pathobiology

Acquired MG is an autoimmune disorder, which results in dysfunction at the NMJ and subsequent weakness. The purpose of the NMJ is to transmit the electrical impulse from the motor neuron to the muscle fiber and trigger contraction. The complex synapse is depicted in **Figure 93.1**. An electrical signal reaching the

TABLE 93.1 Subgroups of Myasthenia Gravis

• Early onset (before 50 y of age); associated with certain HLA haplotypes, 3 times more likely in females
• Late onset (50 y or older); distinct HLA haplotypes; males slightly outnumber females[a]
• Thymoma (10%)
• MuSK (1%-10%)
• LRP4 (1%-3%)
• Seronegative
• Ocular (15%)

Abbreviations: HLA, human leukocyte antigen; LRP4, lipoprotein receptor–related protein 4; MG, myasthenia gravis; MuSK, muscle-specific tyrosine kinase.

[a]Early and late onset account for two-thirds of MG patients.

FIGURE 93.1 The neuromuscular junction. Key components of the neuromuscular junction are depicted including the motor axon and muscle endplate, the synaptic cleft, and the muscle fiber. When an action potential reaches the terminal, acetylcholine (ACh) is released into the synapse and binds to the nicotinic ACh receptors on the sarcolemma, triggering a muscle fiber action potential and contraction. The antigenic targets in myasthenia gravis (MG) and Lambert-Eaton myasthenic syndrome (LEMS) are indicated, as is the site of action of botulinum toxin. Abbreviations: LRP4, lipoprotein receptor–related protein 4; MuSK, muscle-specific tyrosine kinase.

terminal motor axon results in the release of acetylcholine (ACh) quanta into the synaptic cleft through fusion of vesicles with the membrane. The released ACh serves as a chemical signal, which then travels across the synaptic cleft and binds to AChR on the postsynaptic muscle fiber membrane, triggering a muscle fiber action potential and subsequent contraction or twitch.

Autoimmune Antibodies

The NMJ is susceptible to autoimmune pathology because there is no blood-nerve barrier to protect the NMJ. The precise mechanisms triggering autoimmunity at the NMJ are unknown, but the thymus is known to play a role.

Extensive research has shown the complex autoimmune nature of MG. Antibodies against the AChR are found in approximately 80% of patients with MG and are of the immunoglobulin (Ig) G1 or IgG3 subclass. False-positive AChR antibodies are extremely rare (<1%) and often are seen in related disorders (Lambert-Eaton myasthenic syndrome [LEMS]) or motor neuron disease. A majority of these are AChR-"binding" antibodies. AChR-"modulating" antibodies are found in less than 1% of MG patients without binding antibodies, and "blocking" antibodies are found in approximately 10% of MG patients without binding antibodies. The polyclonal IgG antibodies to AChR are produced by plasma cells in peripheral lymphoid organs, bone marrow, and thymus. These cells are derived from B cells that have been activated by antigen-specific T-helper (CD41) cells. The T cells have also been activated, in this case, by binding to AChR antigenic peptide sequences (epitopes) that rest on the histocompatibility antigens on the surface of antigen-presenting cells.

Most common are anti-AChR binding antibodies, which bind to the AChR on the postsynaptic membrane and cause the complement-mediated destruction of the junctional folds and accelerate internalization and degradation of AChR. Blocking antibodies prevent ACh binding to the AChR. Modulating antibodies distort the NMJ and folds. The end result in all cases is a loss of functional AChR.

The AChR antibodies react with multiple determinants, and enough antibodies circulate to saturate up to 80% of all AChR sites on muscle. A small percentage of the anti-AChR molecules interfere directly with the binding of ACh, but the major damage to endplates seems to result from actual loss of receptors owing to complement-mediated lysis of the membrane and to acceleration of normal degradative processes (internalization, endocytosis, lysosomal hydrolysis) with inadequate replacement by new synthesis. As a consequence of the loss of AChR and the erosion and simplification of the endplates, the amplitude of miniature endplate potentials is about 20% of normal, and patients are abnormally sensitive to the competitive antagonist curare. The characteristic decremental response to repetitive stimulation of the motor nerve reflects failure of endplate potentials to reach threshold so that progressively fewer fibers respond to arrival of a nerve impulse. Most AChR antibodies are directed against antigenic determinants on the extracellular portion of the protein farthest out from the membrane rather than the ACh-binding site. The summed effects of the polyclonal anti-AChR antibodies, especially those that fix complement, result in destruction of the receptors. Physiologic studies indicate impaired postsynaptic responsiveness to ACh, which accounts for the physiologic abnormalities, clinical symptoms, and beneficial effects of drugs that inhibit acetylcholinesterase.

The complement pathway is a critical component of innate immunity and involves activation of a cascade of more than

30 proteins. In MG, complement is activated via the classical pathway by antigen-antibody complex triggering the cascade of many proteins with C5 activation as one of the final steps resulting in activation of the membrane attack complex, ultimately leading to destruction of the postsynaptic membrane of the NMJ. The role of complement in MG has led to the development of treatments, which inhibit complement.

The MuSK protein is localized to the inner surface of the muscle membrane and is involved in AChR clustering. Approximately 10% of all patients with MG and 50% of patients without antibodies to the AChR will have antibodies against MuSK. There is prominent atrophy of muscles in anti-MuSK MG. Anti-MuSK antibodies are pathogenic by inhibiting the clustering of the AChR, demonstrated in passive transfer of human IgG from patients with anti-MuSK MG to rodents.

Beginning in 2011, multiple groups of researchers found other antigenic targets in seronegative MG patients. LRP4 is essential for NMJ formation; it is a transmembrane protein serving as an agrin receptor and participating in agrin-activated MuSK and AChR clustering. Antibodies against LRP4 (mainly IgG1 subtype) were found in MG patients seronegative for AChR antibodies and MuSK antibodies. Antibodies against agrin were identified in patients both with anti-AChR antibodies and in seronegative patients. Antibodies against cortactin, another downstream protein involved in AChR clustering have also been found not only in seronegative patients but also in other autoimmune conditions. There are likely additional autoantibodies to components of the NMJ, which are yet to be discovered and account for the remainder of the "seronegative" MG patients.

T Cell Autoimmunity

How the autoimmune disorder begins is not known, but it is T cell–dependent and antibody-mediated process. In human disease, in contrast to experimental MG in animals, the thymus gland is almost always abnormal; often, multiple lymphoid follicles show germinal centers ("hyperplasia of the thymus"), and in about 15% of patients, there is an encapsulated benign tumor, a thymoma. These abnormalities are impressive because the normal thymus is responsible for the maturation of T cells that mediate immune protection without promoting autoimmune responses. AChR antibodies are synthesized by B cells in cultures of hyperplastic thymus gland. The hyperplastic glands contain all the elements needed for antibody production: class II HLA-positive antigen-presenting cells, T-helper cells, B cells, and AChR antigen; that is, messenger RNA for subunits of AChR has been detected in thymus, and "myoid cells" are found in both normal and hyperplastic thymus. The myoid cells bear surface AChR and contain other muscle proteins. When human myasthenic thymus was transplanted into severely congenitally immunodeficient mice, the animals produced antibodies to AChR that bound to their own motor endplates, even though weakness was not evident.

T lymphocytes are responsible for initiating and maintaining the autoantibody response, and the thymus gland is the site of overt pathology. About 70% of thymus glands from adult patients with MG are not involuted, weigh more than normal, and demonstrate lymphoid hyperplasia. In contrast, germinal centers in nonmyasthenics are numerous in the lymph nodes and spleen but are sparse in the thymus. Immunocytochemical methods indicate that the thymic germinal centers in myasthenics contain B cells, plasma cells, HLA class II DR-positive T cells, and dendritic cells. Approximately 10% of patients with MG will have lymphoepithelial thymomas, and the neoplastic thymic epithelial cells express self-antigens including the AChR and other skeletal muscle proteins such as titin and the ryanodine receptor. The lymphoid cells in these tumors are T cells; the neoplastic elements are epithelial cells. Benign thymomas may nearly replace the gland with only residual glandular material at the edges, or they may rest within a large hyperplastic gland. Thymomas tend to occur in older patients, but in one series, 15% were found in patients between ages 20 and 29 years. They may invade contiguous pleura, pericardium, or blood vessels or seed onto more distant thoracic structures, including the diaphragm; however, they almost never spread to other organs. In older patients without thymoma, the thymus gland appears involuted, often showing hyperplastic foci within fatty tissue on microscopic examination of multiple samples. Excessive and inappropriately prolonged synthesis of thymic hormones that normally promote differentiation of T-helper cells may contribute to the autoimmune response. Still, another possible initiating factor is immunogenic alteration of the antigen AChR at endplates; penicillamine therapy in patients with rheumatoid arthritis may initiate a syndrome that is indistinguishable from MG except that it subsides when administration of the drug is stopped.

New Insights

There are few familial cases of the acquired autoimmune disease, but disproportionate frequency of some HLA haplotypes (B8, DR3, DQB1) in MG patients suggests that genetic predisposition may be important. Other autoimmune diseases also seem to occur with increased frequency in patients with MG, especially hyperthyroidism and other thyroid disorders, SLE, rheumatoid arthritis, pernicious anemia, and pemphigus.

MicroRNAs (miRNAs) have recently been shown to be dysregulated in MG and a potential biomarker for MG disease severity. miRNAs are small, noncoding endogenous RNA molecules that are associated with many biologic processes as well as with many human diseases. Studies have shown the upregulation of specific profiles of miRNAs in AChR antibody–positive MG and MuSK antibody–positive MG, with dynamic changes in levels after thymectomy or with immunotherapy.

While overt inflammation is generally absent in the muscle, there is some evidence that the muscle is not a passive target in MG but rather that it responds dynamically. Numerous cytokines are upregulated in the muscle of experimental models of MG. Complement activation at the postsynaptic muscle membrane does not induce apoptosis, but significant activation of molecular transcription and signaling pathways in response.

Interest in the gut microbiome as it relates to autoimmune disease has increased significantly in recent years, particularly those with an imbalance of T-cell populations such as multiple sclerosis and rheumatoid arthritis. Large amounts of microorganisms live in the human gut in a symbiotic relationship that coevolved with the gut-associated lymphoid tissue. While there have not been any studies in humans on the gut microbiome alterations in MG, in animal models there is evidence that probiotics can alter disease course.

Diagnosis

The symptoms of MG have three general characteristics that together provide a diagnostic combination (Table 93.2). Formal diagnosis depends on clinical features, demonstration of the response to cholinergic drugs, electrophysiologic evidence of abnormal neuromuscular transmission, and demonstration of circulating antibodies to AChR or MuSK.

TABLE 93.2 Cardinal Clinical Features of Myasthenia Gravis

• **Fluctuating weakness**
  • Proximal arms or legs
  • Sometimes distal arms/hands
  • Axial: neck flexors > neck extensors

• **Diplopia**
  • Extraocular muscle weakness
  • May resemble INO

• **Ptosis**   • Often asymmetric

• **Dysarthria**
  • Nasal speech
  • LMN

• **Dysphagia**

• **Respiratory insufficiency**
  • Dyspnea
  • Hypoxia is a late finding.

Abbreviations: INO, internuclear ophthalmoplegia; LMN, lower motor neuron.

Clinical Features

The fluctuating nature of myasthenic weakness is unlike any other disease. The weakness varies in the course of a single day, sometimes within minutes, and it varies from day to day or over longer periods. Major prolonged variations are termed *remissions* or *exacerbations*; when an exacerbation involves respiratory muscles to a degree that intubation and assisted mechanical ventilation, it is called a *crisis*. An "exacerbation" may be ameliorated by noninvasive ventilation or may be a transient worsening without respiratory distress. Variations sometimes seem related to exercise; this and the nature of the physiologic abnormality have long been termed *excessive fatigability*, but there are practical reasons to de-emphasize fatigability as a central characteristic of MG. Patients with the disease less often complain of fatigue or symptoms that might be construed as fatigue except when there is incipient respiratory muscle weakness. Myasthenic symptoms are always owing to weakness and not to rapid tiring. Fatigue is common in MG, and at times can be difficult (especially for patients) to differentiate from true myasthenic exacerbation.

The second characteristic of MG is the distribution of weakness. Ocular muscles are affected first in about 40% of patients and are ultimately involved in about 85%. Ptosis and diplopia are the symptoms that result. Other common symptoms affect facial or oropharyngeal muscles, resulting in dysarthria, dysphagia, and limitation of facial movements. Together, oropharyngeal and ocular weakness cause symptoms in virtually all patients with acquired MG. Limb and neck weakness is also common in conjunction with cranial weakness. Almost never are the limbs affected alone. MuSK myasthenia particularly involves ocular, facial, and bulbar muscles and has high risk of respiratory insufficiency. MuSK myasthenia can follow a rapidly progressive and more severe course.

Aside from the fluctuating nature of the weakness, MG is not a steadily progressive disease. The general nature of the disease, however, is usually established within weeks or months after the first symptoms. If myasthenia is restricted to ocular muscles for 2 years, certainly if it is restricted after 3 years, it is likely to remain restricted, and only in rare cases does it then become generalized. Distinguishing solely ocular myasthenia from generalized myasthenia soon after onset is challenging.

Vital signs and findings on general physical examination are usually normal, unless the patient is in crisis. Weakness of the facial and levator palpebrae muscles produces a characteristic expressionless appearance with drooping eyelids, which can be asymmetric (**Fig. 93.2A**). Weakness of ocular muscles (**Fig. 93.2B**) may cause paralysis or weakness of isolated ocular muscles, limitation of conjugate gaze, complete ophthalmoplegia in one or both eyes, or a pattern resembling internuclear ophthalmoplegia. Proximal limb weakness is manifest by difficulty in raising the arms above the head (**Fig. 93.2C**) and difficulty climbing stairs, whereas weakness of the neck flexor and extensor muscles may result in head drop (**Fig. 93.2D**). Weakness of oropharyngeal or limb muscles, when present, can be shown by appropriate tests. Respiratory muscle weakness can be detected by pulmonary function tests, which should not only be limited to measurement of vital capacity but should also include inspiratory and expiratory pressures, the measurement of which may be abnormal even before overt symptoms are evident. Muscular wasting of variable degree is found in about 10% of patients but is not focal and is usually encountered only in patients with malnutrition caused by severe dysphagia. Fasciculations do not occur, unless the patient has received excessive amounts of cholinergic drugs. Sensation is normal, and the reflexes are preserved, even in muscles that are weak.

Crisis is most likely to occur in patients with oropharyngeal or respiratory muscle weakness. It seems to be provoked by respiratory infection in many patients or by surgical procedures, including thymectomy, although it may occur with no apparent provocation. Both emotional stress and systemic illness may aggravate myasthenic weakness for reasons that are not clear; in patients with oropharyngeal weakness, aspiration of secretions may occlude lung passages to cause rather abrupt onset of respiratory difficulty. Major surgery may be followed by respiratory weakness without aspiration, however, so this cannot be the entire explanation.

Clear clinical picture of fluctuating weakness, improved with rest, and ocular symptoms can make diagnosis of MG straightforward. However, ocular MG can at times be challenging to diagnose when clinical signs are minimal during examination, symptoms do not significantly fluctuate, and symptoms are mild. The ice test is performed at bedside on patients with ptosis: A pack of ice is placed over the ptotic eye for 1 to 2 minutes, and resolution or improvement in the ptosis is considered positive and highly specific for MG.

The dramatic improvement that follows the injection of neostigmine bromide (Prostigmin) or edrophonium (Tensilon) made the use of these drugs helpful in the diagnosis of MG. Despite the overall low risk of complications, because of the need to have atropine and a crash cart when administering these drugs, this test is hardly performed currently. The Tensilon test administers the short-acting acetylcholinesterase inhibitor edrophonium; improvement in a subsequent clinical assessment is considered similarly positive and specific for MG. A test dose of 2-mg edrophonium is given intravenously, followed by up to 8 mg intravenously. Muscles weak from MG will respond within 30 to 45 seconds, with a response lasting up to 5 minutes; an objective improvement in muscle strength is considered a positive result. Although risk of serious cardiac complications is low, life-threatening bradyarrhythmias and ventricular fibrillation can occur with the Tensilon test, and it should be carried

FIGURE 93.2 Clinical features of myasthenia gravis. **A:** Bifacial weakness and asymmetric ptosis. **B:** Weakness of extraocular muscles causing dysconjugate gaze. **C:** Proximal arm weakness. **D:** Neck flexor weakness causing head drop. (Courtesy of C. M. Ulane.)

out with close monitoring and atropine at the bedside. False positives can occur in motor neuron and other diseases, and the sensitivity of the Tensilon test is 60%. Both the ice test and Tensilon test require objectively measurable outcomes and thus are most useful in cases of ptosis and oculomotor abnormalities, rather than limb weakness. The only other conditions in which clinical improvement has been documented after use of edrophonium are other disorders of neuromuscular transmission: botulinum intoxication, snake bite, organophosphate intoxication, or unusual disorders that include features of both MG and the Lambert-Eaton syndrome. Denervating disorders, such as motor neuron disease or peripheral neuropathy, do not show a reproducible or unequivocal clinical response to edrophonium or neostigmine.

Laboratory Testing and Electrophysiologic Testing

Routine examinations of blood, urine, and cerebrospinal fluid are normal. Antibodies to AChR are found in 85% to 90% of patients of all ages with generalized MG if human muscle is used as the test antigen (**Table 93.3**). Antibodies may not be detected in patients with strictly ocular disease, in some patients in remission (or after thymectomy), or even in some patients with severe symptoms. The titer does not match the severity of symptoms; patients in complete clinical remission may have high titers. For pure ocular MG, AChR antibodies present in serum support the diagnosis; however, the sensitivity is rather low (range, 25%-70%). Antibodies to myofibrillar proteins (titin, myosin, actin, actomyosin) are found in 85% of patients with thymoma and may be the first evidence of thymoma in some cases. In the first report of seronegative myasthenia, there were no clinical differences between patients who had or lacked AChR antibodies. Subsequently, more than half of these seronegative patients were found to have antibodies to MuSK. Patients with anti-MuSK antibodies were found to have a similar clinical picture almost always with generalized MG with predominantly bulbar signs, poor and inconsistent responses to pyridostigmine, immunosuppressants, or thymectomy but excellent response to plasmapheresis. Antibodies to rapsyn-clustered AChR were detected on human embryonic kidney cells by fluorescence-activated cell sorting in 66% (25/38) of sera from

TABLE 93.3 Diagnostic Testing for Myasthenia Gravis

Laboratory Test	Comments
AChR antibodies	
• AChR binding • AChR blocking • AChR modulating	• 80%-85% of all MG • 50% of ocular MG • Binding most common • Blocking positive in ~10% of MG with negative binding • Modulating positive in <1% of MG with negative binding
MuSK antibodies	• 10% of all MG • 50% of AChR-negative MG
Other antibodies	
• Striational • Titin, RyR, myosin, actin • LRP4, agrin	• Present in 75%-85% of thymomatous MG, frequent in ICI-induced MG • May be associated with more severe disease (titin, RyR) • LRP4 present in 1%-3% of MG; both may be found in other disorders.
Electrodiagnostic Test	
Nerve conduction studies	• Repetitive nerve stimulation reveals decrement (≥10%). • Sensitivity 53%-100% in generalized MG • Sensitivity 10%-48% in ocular MG • Not specific
Single-fiber EMG	• Most sensitive test for MG (>95%) but not specific (~70%)
Radiology	
Computed tomography of the chest	• 10% thymoma

Abbreviations: AChR, acetylcholine receptor; EMG, electromyography; ICI, immune checkpoint inhibitor; LRP4, lipoprotein receptor–related protein 4; MG, myasthenia gravis; MuSK, muscle-specific tyrosine kinase; RyR, ryanodine receptor.

FIGURE 93.3 Repetitive nerve stimulation (RNS). Slow (3 Hz) RNS of the median nerve-abductor pollicis brevis system reveals normal response, decrement and facilitation of the compound muscle action potential. **A:** Normal response to RNS with minimal decrement. **B:** Decremental response in myasthenia gravis. **C:** Facilitation in Lambert-Eaton myasthenic syndrome and botulism.

patients that had previously tested negative for binding to AChR in solution. Other serologic abnormalities are encountered with varying frequency, and in several studies, antinuclear factor, rheumatoid factor, and thyroid antibodies were encountered more often than in control populations.

Recently, antibodies against lipoprotein-related protein 4 (LRP4) were discovered in "seronegative" MG patients, ranging in frequency from 1% to 3%. LRP4 is expressed in the postsynaptic muscle and activates MuSK and binds agrin, critical components of NMJ signal transmission.

The characteristic electrodiagnostic abnormality is progressive decrement in the amplitude of compound muscle action potentials evoked by repetitive nerve stimulation at 3 or 5 Hz (Fig. 93.3). In generalized MG, the decremental response can be demonstrated in about 90% of patients if at least three neuromuscular systems are used (median-thenar, ulnar-hypothenar, accessory-trapezius). Repetitive nerve stimulation testing is often negative in ocular MG (in both distal and proximal muscles). In single-fiber electromyography (EMG), a small electrode measures the interval between evoked potentials of the muscle fibers in the same motor unit. This interval normally varies, a phenomenon called *jitter*, and the normal temporal limits of jitter have been defined. In MG, the jitter is increased, and an impulse may not appear at the expected time; this is called *blocking*, and the number of blockings is increased in myasthenic muscle. All these electrophysiologic abnormalities are characteristic of MG, but blocking and jitter are also seen in other disorders. Single-fiber EMG is the most sensitive test for MG but is not specific.

The standard-needle EMG is usually normal, occasionally shows a myopathic pattern, and almost never shows signs of denervation unless some other condition supervenes. Similarly, nerve conduction velocities are normal.

All patients diagnosed with MG should be screened for the presence of thymoma. Computed tomography (CT) of the mediastinum demonstrates all but microscopic thymomas. Magnetic resonance imaging (MRI) is not more sensitive than CT.

The differential diagnosis includes all diseases that are accompanied by weakness of oropharyngeal or limb muscles, such as the muscular dystrophies, amyotrophic lateral sclerosis, progressive bulbar palsy, ophthalmoplegia of other causes, and the asthenia of psychoneurosis or hyperthyroidism. There is usually no difficulty in differentiating these conditions from MG by the findings on examination and by the failure of symptoms in these conditions to improve after parenteral injection of neostigmine or edrophonium. Occasionally, blepharospasm is thought to mimic ocular myasthenia, but the forceful eye closure in that condition involves both the upper and the lower lids; the narrowed palpebral fissure and signs of active muscle activity are distinctive.

Management

Treatment for MG is tailored to the individual patient. A general algorithm for treatment of MG is presented in Figure 93.4. Clinicians must choose the sequence and combination of therapy: anticholinesterase drug therapy, corticosteroids, immunosuppressives, plasmapheresis, intravenous immunoglobulins (IVIG), biologics (monoclonal antibodies) and thymectomy (Table 93.4).

Acetylcholinesterase Inhibitors

In 1934, Dr. Mary Walker discovered the beneficial effects of acetylcholinesterase inhibitors in patients with MG. To this day, this remains a mainstay of treatment, yet there are no randomized trials of these agents in MG. A Cochrane review in 2011 reaffirmed the lack of controlled studies but concluded that the results from observational studies were so clear that it would be difficult to justify a trial. It is generally agreed that anticholinesterase drug therapy should be given as soon as the diagnosis is made. Of the three available drugs—neostigmine, pyridostigmine bromide, and ambenonium—pyridostigmine is the most popular but has not been formally assessed in controlled comparison with the other drugs. The muscarinic side effects of abdominal cramps and diarrhea are the same for all three drugs but are least severe with pyridostigmine; none has more beneficial or adverse effects than another and all can be regarded as safe. The usual starting dose of pyridostigmine is 60 mg given orally every 4 hours while the patient is awake. Depending on clinical response, the dosage may be increased, but incremental benefit is not to be expected in amounts greater than 120 mg every 2 hours. If patients have difficulty eating, doses can be taken about 30 minutes before a meal. If patients have special difficulty on waking in the morning, an extended-release 180-mg tablet of pyridostigmine can be taken at bedtime. Muscarinic symptoms can be ameliorated by preparations containing atropine (0.4 mg) with each dose of pyridostigmine. Excessive doses of atropine can cause psychosis, but the amounts taken in this regimen have not had that effect. Other drugs may be taken if diarrhea is prominent. Combinations of two drugs are no better than any single drug alone.

Although cholinergic drug therapy sometimes gives impressive results, there are serious limitations. In ocular myasthenia, ptosis may be helped, but some diplopia almost always persists. In generalized MG, patients may improve remarkably, but some symptoms usually remain. Cholinergic drugs do not return function to normal, and the risk of crisis persists because the disease is not cured. Therefore, one of the other treatments is used promptly to treat generalized MG. MuSK MG patients often do not respond as well to anticholinesterases.

Glucocorticoids

Despite the widespread use and agreed upon efficacy of glucocorticoids in the treatment of MG, there are no randomized controlled studies, and at this point, it would be unethical to withhold a known beneficial treatment. Several controlled and blinded studies initially suggested the benefit of steroids for MG. Numerous retrospective studies show that steroids can induce remission in 27% to 42% and marked improvement in 29% to 52% of patients with MG. Prednisone, 60 to 100 mg daily, will achieve a response within a few days or weeks. Within the first 2 weeks of starting prednisone, patients may experience worsening of their symptoms, and caution must be taken in those with prominent bulbar or respiratory symptoms. An equally satisfactory response can be seen with a lower dosage, but it takes longer; for instance, if the dose is 25 to 40 mg, benefit may be seen in 2 to 3 months. Once improvement is achieved, the dosage should be gradually tapered to 20 to 35 mg every other day. This has become a popular treatment for disabled patients, but there has been no controlled trial. If the patient does not improve in about 6 months or if there are unacceptable side effects from the steroids, treatment with steroid-sparing agents is pursued.

Prednisone, 15 to 35 mg on alternate days, is also recommended by some clinicians for ocular myasthenia, weighing risks against potential benefit. For some patients in sensitive occupations, the risks of prednisone therapy may be necessary (eg, actors, police officers, roofers or others who work on heights, or those who require stereoscopic vision). Ocular myasthenia is not a threat to life, and pyridostigmine may alleviate ptosis. An

FIGURE 93.4 General treatment guidelines for myasthenia gravis (MG). Treatment of MG is highly individualized and depends on many factors. Shown here are general principles to guide physicians in the treatment of MG based on severity of symptoms. Abbreviations: IVIG, intravenous immunoglobulins; PE, plasma exchange.

TABLE 93.4 Medications Used to Treat Myasthenia Gravis

Agent	Dose	Monitoring Parameters	Side Effects
Pyridostigmine	30-90 mg q4-6h Extended release: 180 mg every night	Clinical response	Common: fasciculations, diarrhea Overdose: cholinergic crisis, weakness, dysphagia, respiratory failure Rare: bromism (acute psychosis)
Prednisone	1 mg/kg/d (usually 60-80 mg/d) Alternate-day dosing Taper over months after sustained clinical response Concomitant: PPIs, H2 blockers Calcium, vitamin D	May cause initial worsening Blood pressure Serum glucose Yearly ophthalmologic exam	Hyperglycemia Hypertension Weight gain Fluid retention Cataracts/glaucoma Osteoporosis/avascular necrosis Steroid myopathy Peptic ulcer disease Depression/psychiatric effects
IVIG	2 g/kg over 4-5 d	Heart rate Blood pressure Clinical response (usually within 1 wk)	Common: headache, chills, fever, nausea Rare: acute renal failure (solute-induced), aseptic meningitis, thrombosis (DVT/PE, stroke, MI), leukopenia
Plasma exchange	Five to six exchanges	Heart rate Blood pressure Coagulation studies Fibrinogen Ionized calcium	Paresthesias Hypotension Transient arrhythmias Nausea, light-headedness, chills Complications of central lines
Azathioprine	Start at 50 mg/d Titrate up to 2-3 mg/kg/d	Complete blood count Hepatic function	Infections Gastrointestinal upset Hepatoxicity Cytopenias Malignancy
Mycophenolate mofetil	1 g twice a day, up to 3 g total daily[a]	Complete blood count Hepatic function	Infections Cytopenias Nausea Diarrhea Abdominal pain If used with other immunosuppressives: PML
Cyclosporine A	5-6 mg/kg twice a day Goal trough: 75-150 ng/mL	Blood pressure Renal function	Infections Renal toxicity Hypertension Many medication interactions
Tacrolimus	3-5 mg/d	Blood pressure Renal function Glucose	Infections Hyperglycemia Renal toxicity Hypertension Malignancy
Cyclophosphamide	Monthly pulsed doses 500 mg/m^2[b]	Complete metabolic panel Urine studies Complete blood count	Myelosuppression Hemorrhagic cystitis Hyponatremia Seizures Opportunistic infection Malignancy

Abbreviations: DVT, deep vein thrombosis; IVIG, intravenous immunoglobulin; MI, myocardial infarction; PE, pulmonary embolism; PML, progressive multifocal leukoencephalopathy; PPIs, proton pump inhibitors.
[a]Recent randomized controlled trials suggest no benefit.
[b]Usually reserved for severe refractory myasthenia gravis.

eye patch can end diplopia, and prisms help some patients with stable horizontal diplopia. Currently, the Efficacy of Prednisone in the Treatment of Ocular Myasthenia trial is ongoing and seeks to study the safety and efficacy of prednisone for ocular MG in a multicenter, randomized controlled trial.

Steroid-Sparing Agents

Azathioprine is one of the most studied in this category. It is a purine antimetabolite, which acts by inhibiting T- and B-cell proliferation. It is often well tolerated, but it can take more than 12 months to achieve maximal benefit. Common side effects include gastrointestinal upset and an idiosyncratic flu-like reaction. In addition, azathioprine may cause hepatotoxicity, and transaminases need to be monitored. Rare but serious adverse effects include leukopenia and pancytopenia, which can occur at any time during treatment. In 1998, a randomized controlled trial demonstrated the benefit of azathioprine in addition to prednisolone. Patients receiving both had fewer exacerbations, longer remission, and lower total daily dose of maintenance prednisolone LEVEL 2.[1] Another study suggests that azathioprine alone may be

as effective or more effective than prednisone alone in preventing clinical deterioration after 2 to 4 years of treatment LEVEL 1.[2]

Mycophenolate mofetil inhibits T- and B-cell proliferation by selectively blocking purine synthesis. Initial pilot and retrospective studies showed promising benefit for the treatment of MG. In one report, 73% of 85 patients improved; adverse effects led to discontinuation of treatment in 6% LEVEL 1.[3] However, two randomized controlled trials in 2008 showed no benefit over placebo LEVEL 1.[4,5] Many experts still use mycophenolate and consider it effective, and it has a favorable side effect profile. Critiques of the negative studies suggested that the patients chosen had mild disease, a better than expected response to low-dose prednisone and the overall short duration of the trial may have obscured a positive effect.

Cyclosporine acts as a calcineurin inhibitor, thus reducing the function of effector T cells. It is used less due to renal toxicity; however, it has been shown to be effective in several randomized, controlled trials LEVEL 1.[6,7]

Cyclophosphamide can also be considered in doses up to 2.5 mg/kg daily for an adult LEVEL 3.[8] It is often reserved for refractory cases due to toxicity. Another agent with benefit is tacrolimus LEVEL 1.[9]

Methotrexate (MTX) may also be considered as a second-line agent for the treatment of MG and had been used despite minimal quality data about its effectiveness. MTX is a selective inhibitor of dihydrofolate reductase, which inhibits nucleic acid synthesis in rapidly dividing cells such as lymphocytes, thus resulting in immunosuppression. Side effects are often mild with mucositis, alopecia, and gastrointestinal intolerance, but serious adverse events such as interstitial pneumonitis, hepatotoxicity, and bone marrow suppression can occur. Recently, a randomized, double-blind, placebo-controlled trial was conducted to assess the efficacy of MTX as a steroid-sparing agent by measuring the primary outcome of area under the dose-time curve. Although there was no difference at up to 12 months in terms of area under the dose-time curve or secondary clinical outcome measures LEVEL 1,[10] the authors note that it is unclear whether the study was underpowered or whether MTX truly does not work for MG. A second study was done assessing the degree of polyglutamation of MTX (which in other diseases correlates with its anti-inflammatory effects) in these same patients at the end of this study. The study group found that the degree of MTX polyglutamation correlated with clinical therapeutic effect for MG.

The numerous side effects of prednisone must be weighed against the possibilities of marrow suppression, susceptibility to infection, or delayed malignancy in patients who are given immunosuppressive drugs.

Plasma Exchange and Intravenous Immunoglobulins

Plasma exchange (PE) is also used for exacerbations; the resulting improvement, seen in most patients, may be slight or dramatic and may last only a few days or several months. PE is safe but expensive and is not convenient for many patients. Indwelling catheters may lead to bleeding, thrombosis, or infection. In general, five sessions of PE are given every other day.

IVIG therapy is usually given in five daily doses to a total of 2 g/kg body weight. There is some evidence that 1 g/kg may be sufficient for treating exacerbation LEVEL 3.[11] A randomized, double-masked, placebo-controlled trial of IVIG for the treatment of moderate to severe MG exacerbations found benefit that was both statistically significant and clinically meaningful LEVEL 3.[12] Side effects include headache, aseptic meningitis, and a flu-like syndrome that can be alarming but subsides in 1 or 2 days. Thromboembolic events, including stroke, can occur. IVIG is easier to administer but is even more expensive. It is preferred over PE in those with poor venous access, including children.

There is recent interest in the use of subcutaneous Ig (SCIg) as an alternative to IVIG for many autoimmune disorders because it provides patients with greater autonomy to self-administer, requiring less health care resources and theoretically has fewer side effects and better tolerability. A systematic review of SCIg in MG found only limited and uncontrolled studies but overall that SCIg may improve disability in MG with only local and mild adverse events.

Both IVIG and PE are also available for management of exacerbations. Given the differences in availability at various treatment centers and different side effect profiles, it is important to consider each carefully. A study compared IVIG to PE for moderate to severe exacerbations in a randomized, masked fashion and found both to be equally effective treatments for worsening MG with similar duration of benefits and safety profiles LEVEL 1.[13]

Other Immunomodulatory Treatments

Rituximab

There is great interest in new immunosuppressive and modulatory therapies to treat MG. Rituximab was originally developed for the treatment of cancer and other autoimmune disorders. It is a monoclonal antibody to $CD20^+$ B-cells, which acts to deplete B-cell reserves. The potential benefits in MG were reported by several groups in retrospective or prospective case series. In addition, there seemed to be a particularly robust response in patients with MuSK antibody MG. A large prospective blinded review comparing MuSK MG patients treated with rituximab compared to other immunosuppressive medications showed that rituximab increased the probability of a favorable clinical outcome. A phase II trial of rituximab (BeatMG study) was a randomized, double-blind, placebo-controlled trial to determine the safety and efficacy of rituximab for AChR antibody–positive generalized MG, failed to meet the primary outcome in terms of steroid-sparing effects; however, overall disease may have been milder, and ad hoc subgroup analysis suggests that rituximab may be more effective in moderate to severe disease. Yet, several retrospective studies suggest a benefit for AChR-positive MG and a meta-analysis showed a 26% response rate for AChR-positive MG patients treated with rituximab. A retrospective study suggests that rituximab is safe and effective for late-onset MG, and in a prospective extended study, rituximab showed sustained clinical improvement for both AChR and MuSK MG. Thus, while evidence more clearly suggests a benefit for MuSK MG, there may be some benefit for certain patients with AChR MG. Rituximab is generally considered safe and well tolerated; however, there is a low risk of progressive multifocal leukoencephalopathy and hepatitis B reactivation.

Complement Inhibition: Eculizumab

Given the role of complement-mediated destruction of the NMJ in MG, interest has grown in the use of complement inhibition as a treatment for MG. Eculizumab is a monoclonal antibody against the terminal C5 component of complement, preventing its activation and therefore inhibiting formation of the membrane attack complex; therefore, it likely functions to preserve AChR and the postsynaptic membrane thus sustaining NMJ transmission in MG.

A large phase III clinical trial (REGAIN) showed major clinical benefits for patients with refractory generalized MG treated with eculizumab compared to placebo for secondary clinical endpoints (even though primary endpoint did not reach significance), leading to U.S. Food and Drug Administration (FDA) approval for use of eculizumab in refractory MG. An open-label extension of REGAIN has shown that benefits of eculizumab treatment remained up to 3 years; clinical parameters including minimal manifestations of disease or pharmacologic remission. The most serious side effect of eculizumab is meningococcal meningitis, which mandates appropriate vaccination prior to initiation of therapy and initial prophylaxis as needed.

Complement Inhibition: Zilucoplan

Zilucoplan is a small synthetic peptide that binds to the C5 component of complement, preventing cleavage and activation of the complement cascade. A phase II randomized, double-blind, placebo-controlled trial explored the efficacy of subcutaneous zilucoplan at two different doses in patients with AChR MG. It was found to be well tolerated and met the primary endpoint of clinically meaningful change in quantitative myasthenia gravis score (QMG) score at week 12 (QMG score is a scale assessing muscle weakness) as well as most secondary endpoints. Maximal complement inhibition at the higher dose of zilucoplan administered demonstrated the most rapid and robust disease suppression, although partial complement inhibition at the lower dose was superior to placebo.

Neonatal Fc Receptor Inhibition

A novel treatment approach involves targeting the neonatal Fc receptor (FcRn). The FcRn plays an essential role in prolonging the half-life of IgG molecules by salvaging them from lysosomal degradation. When the FcRn is inhibited, IgG half-life is significantly reduced, and both total IgG levels and pathogenic IgG autoantibody levels are reduced.

Efgartigimod

Efgartigimod is a monoclonal antibody against FcRn, preventing lysosomal degradation of circulating IgG. It is administered by intravenous infusion. Single-dose administration causes a 50% reduction in IgG levels and repeated dosing further lowers IgG levels by 75%. A randomized, double-blind, placebo-controlled trial of efgartigimod in patients with generalized AChR antibody–positive MG showed very promising results. Not only was it safe and well tolerated, the trial demonstrated a correlation between reduced AChR antibody levels and disease improvement, and several different efficacy scales demonstrated that 75% of patients had rapid and long-lasting disease improvement.

Other Neonatal Fc Receptor Inhibitors

Rozanclixizumab is a subcutaneous monoclonal antibody against the FcRn for which a recent phase II study reported clinically meaningful improvements in patients with MG with concomitant reductions in autoantibody titers (results to be published). Other FcRn inhibitors being investigated include nipocalimab and RVT-1401.

Other Treatments

Additional interest is ongoing in several other emerging therapies for MG. These include numerous other mechanisms of B-cell inhibition (bortezomib—a proteasome inhibitor that depletes short and long-lived B cells); belimumab, monoclonal antibody against the B cell–activating factor, which inhibits differentiation of B cells; and stem cell therapy (marrow depletion followed by autologous hematopoietic stem cell transplantation).

Tirasemtiv, an investigational drug that activates the fast skeletal muscle troponin complex, was studied as a means to increase strength and reduce muscle fatigue in MG by amplifying downstream muscle response in a hypothesis-generating phase II double-blind, placebo-controlled, randomized study. It was found to be well tolerated and may improve function in MG, with dose-related improvements in QMG scores.

Case reports have shown beneficial effects for refractory MG with the use of tocilizumab (anti–interleukin 6 receptor monoclonal antibody) and ofatumumab (fully human monoclonal antibody against a distinct CD20 B-cell epitope).

Thymectomy

Thymectomy was originally reserved for patients with serious disability because the operation had a high mortality. With advances in surgery and anesthesia, however, the operative mortality is now negligible in major centers. Although thymectomy had been a mainstay of treatment for MG, there had been no conclusive evidence regarding its benefit until the completion and publication in 2017 of the thymectomy trial in non-thymomatous myasthenia gravis patients receiving prednisone therapy (MGTX) trial, a multicenter, international randomized, rater-blinded trial of extended transsternal thymectomy plus alternate-day prednisone compared to alternate-day prednisone alone. This trial demonstrated that thymectomy for nonthymomatous AChR antibody–positive MG is probably more effective than prednisone alone in terms of achieving minimal manifestation status, lower dose of prednisone, reduced need for other immunosuppressives or rescue therapy, and reduced hospitalizations at 3 years LEVEL 1.[14] Approximately half of the patients participated in an extension study showing that these benefits persisted at 5 years. A systematic review and meta-analysis found that thymectomy may be considered effective as treatment for nonthymomatous MG with significantly higher remission rates. Thus, expert guidelines recommend that thymectomy be discussed with nonthymomatous AChR antibody–positive MG patients who are between the ages of 18 and 65 years of age. There are no randomized controlled trials for MuSK or seronegative MG and the role of thymectomy; however, a retrospective review of MuSK MG data collected for a trial of rituximab found that thymectomy was not associated with additional clinical improvement in patients with MuSK MG.

Decisions made for children, patients older than 65 years, and seronegative MG must be individualized. Although the trial demonstrated thymectomy to be safe, it is still a major operation. Minimally invasive techniques are available, but these have the potentially higher risk of leaving residual thymic tissue. Mantegazza et al found a remission rate of about 50% at 6 years after surgery with either the standard transsternal operation or a minimally invasive thoracoscopic operation.

Patients with thymoma are likely to have more severe MG and are less likely to improve after thymectomy; nevertheless, many of these patients also improve if the surrounding thymus gland is excised in addition to the tumor.

Myasthenic Crisis

Myasthenic crisis arises in about 10% of myasthenic patients. It is more likely to occur in patients with dysarthria, dysphagia, and documented respiratory muscle weakness, presumably

TABLE 93.5 Signs of Impending Respiratory Failure in Myasthenia Gravis

Clinical features	Significant bulbar dysfunction • Dysarthria, dysphagia • Impaired gag reflex Tachypnea, dyspnea Use of accessory muscles Paradoxical breathing Count out loud in single exhale Poor cough Impaired secretion clearance
Laboratory signs	**Pulmonary function tests:** VC <15-20 mL/kg (or VC <1 L) NIF > −20 cm H_2O MEP <40 cm H_2O Tidal volume <4-5 mL/kg **Laboratory:** Pco_2 ≥50 mm Hg[a]

Abbreviations: MEP, maximal expiratory pressure; NIF, negative inspiratory force; VC, vital capacity.
[a]Hypoxia is a late finding.

TABLE 93.6 Medications That Exacerbate Myasthenia Gravis

Contraindicated	α-Interferon Penicillamine Telithromycin Botulinum toxin
Use with caution (may worsen MG)	**Cardiac medications** • β-Blockers (propranolol, timolol maleate eye drops) • Calcium channel blockers • Quinine, quinidine, procainamide **Neuromuscular blocking agents** • Succinylcholine • d-Tubocurarine **Antibiotics** • Aminoglycosides (gentamicin, kanamycin, streptomycin, neomycin) • Macrolides (erythromycin, azithromycin) • Quinolones (ciprofloxacin, levofloxacin, norfloxacin, ofloxacin) **Magnesium salts** (laxatives, antacids)

Abbreviation: MG, myasthenia gravis.

because they are liable to aspirate oral secretions, but crisis may also occur in other patients after respiratory infection or major surgery (including thymectomy). The principles of treatment are those of respiratory failure in general. Numerous retrospective studies have investigated what clinical and laboratory factors in MG crisis predict the need for mechanical ventilation. See **Table 93.5** for clinical and laboratory features of impending respiratory failure in patients with MG. Cholinergic drug therapy is usually discontinued once an endotracheal tube has been placed and positive pressure respiration started; this practice avoids questions about the proper dosage or cholinergic stimulation of pulmonary secretions. Crisis is viewed as a temporary exacerbation that subsides in a few days or weeks. The therapeutic goal is to maintain vital functions and to avoid or treat infection until the patient spontaneously recovers from the crisis. Cholinergic drug therapy need not be restarted unless fever and other signs of infection have subsided, there are no pulmonary complications, and the patient is breathing without assistance. Myasthenic crisis and exacerbations can be triggered by infections, surgery, and medications (**Table 93.6**).

Vaccination in Myasthenia Gravis

A population-based cohort study in Canada found that patients with MG are at a 39% higher risk of serious infections compared to matched controls, although this study did not account for the use of immunosuppressant medication. Given the importance of vaccines in preventing spread of infectious disease at the population level and the role in preventing serious infectious disease in patients with MG, vaccine safety for is often of great concern to patients with MG. Safety of vaccination in autoimmune diseases is not well studied but small, observational studies have suggested that influenza vaccination in MG is safe and does not affect AChR antibody titers in patients with MG. A randomized, double blind, placebo-controlled trial in AChR antibody–positive MG patients showed that influenza vaccination is safe and did not result in MG exacerbation and induced an immune response comparable to controls and independent of immunosuppression.

Pregnancy and Myasthenia Gravis

MG affects women of childbearing age, and pregnancy presents a unique situation. Although MG itself does not affect fertility, immunosuppressive medications can affect fertility and have teratogenic effects.

It is difficult to predict the course of MG during pregnancy due to high variability. One third of women experience first-trimester worsening of MG; however, there may be improvement or remission in the second and third trimesters.

Ideally, the patient should meet with her neurologist to discuss pregnancy planning as early as possible. One consideration is thymectomy if not already performed, given the benefits for patients with MG, and that thymectomy may be associated with lower likelihood of neonatal myasthenia.

Treatment of choice during pregnancy is pyridostigmine and corticosteroids at the lowest effective dose. It is not recommended to begin other immunosuppressives during pregnancy due to long time of onset to benefit and potential harm to infant. Patients who are already taking cyclosporine or azathioprine therapy can be continued if needed, whereas MTX and mycophenolate mofetil should be discontinued prior to pregnancy. Rituximab may be safe during pregnancy, but there is a lack of information and current recommendations suggest discontinuing for 12 months prior to pregnancy.

Exacerbations may be treated with IVIG and PE as needed.

Outcome

Before the advent of intensive care units and the introduction of positive pressure respirators in the 1960s, crisis was a life-threatening event. In the past 60 to 70 years, advances in pulmonary critical care and in the diagnosis of MG have reduced mortality rates for myasthenic crisis from 33% to 60% to approximately 4%. With improved respiratory care, patients rarely die of MG, except when cardiac, renal, or other disease complicates the picture. Even so, pulmonary intensive care is now so effective that crisis is almost never fatal and many patients go into a remission after recovery from crisis. Because of advances in therapy, MG is still serious but not so grave.

CONGENITAL MYASTHENIC SYNDROMES

Neonatal Myasthenia Gravis

About 12% of infants born to myasthenic mothers have a syndrome characterized by impaired sucking, weak cry, limp limbs, and, exceptionally, respiratory insufficiency. Symptoms begin in the first 48 hours and may last several days or weeks, after which the children are normal. The mothers are usually symptomatic but may be in complete remission; in either case, AChR antibodies are demonstrable in both mother and child. Symptoms disappear as the antibody titer in the infant declines. Severe respiratory insufficiency may be treated by exchange transfusion, but the natural history of the disorder is progressive improvement and total disappearance of all symptoms within days or weeks. Respiratory support and nutrition are the key elements of treatment. Rare instances of arthrogryposis multiplex congenita (a syndrome of multiple joint contractures present at birth) have been attributed to transplacental transfer of antibodies that inhibit fetal AChR.

Congenital Myasthenic Syndromes

Congenital myasthenic syndromes (CMS) comprise at least 30 distinct entities, with many recently discovered due to both increased awareness and use of next-generation sequencing methods. The most common and well defined will be considered here.

Children with congenital MG, although rarely encountered, show several characteristics. The mothers are asymptomatic and do not have circulating anti-AChR in the blood. Usually, no problem occurs in the neonatal period; instead, ophthalmoplegia is the dominant sign later in infancy. Limb weakness may be evident. The condition is often familial. Antibodies to AChR are not found, but there are decremental responses to repetitive stimulation. The CMS may be classified according site of pathology: presynaptic, synaptic, postsynaptic.

Presynaptic Congenital Myasthenic Syndromes

Presynaptic CMS results from defects in genes encoding for proteins essential for neuromuscular transmission along the presynaptic nerve terminal membrane. Most common is the choline acetyltransferase deficiency, which prevents the synthesis of ACh. Some infants may be severely hypotonic and apneic at birth, whereas others may be normal at birth but develop sudden and seemingly unprovoked episodes of apnea. Severity of this disease is associated with site of genetic mutation.

SNAP-25B deficiency is due to a defect in initiating formation of synaptic vesicle exocytosis at the endpoint, resulting in reduced number of ACh containing quanta at the nerve terminal with each nerve impulse.

Paucity of synaptic vesicles and reduced quantal release syndrome has not had a genetic defect identified.

Synaptotagmin 2 deficiency affects calcium sensing in the presynaptic nerve terminal.

Synaptic Basal Lamina-Associated Syndromes

Deficiency of acetylcholinesterase at the endplate may be due to mutations in COLQ, which is responsible for anchoring acetylcholinesterase to the basal lamina. Deficiency results in prolonged synaptic currents and action potentials due to increased ACh in the synaptic space. Patients may be severely affected at birth or develop symptoms later on. Weakness may present in a limb-girdle distribution.

Laminin-B2 deficiency results in misalignment of the nerve terminal with the postsynaptic region. This results in reduced quantal release, and other organs may be affected such as the kidney.

Defects in the Acetylcholine Receptor

One of the most common CMS results from defects in the muscle nicotinic AChR. Primary AChR deficiency occurs from different types of mutations, but the end result is that endplate AChR is reduced to approximately 10% of the normal concentration, and the response to ACh in the synapse is significantly reduced. Most patients have ptosis, ophthalmoplegia that becomes fixed, and variable limb weakness.

The slow-channel syndrome results from dominant mutations in the ligand-binding pore of the AChR and results in prolonged synaptic currents and action potentials. This triggers a repetitive compound motor action potential, which is enhanced by edrophonium and a depolarization block on repetitive stimulation. Cervical, scapular and dorsal forearm muscles are often affected and ocular muscles are usually spared.

The fast-channel syndrome is caused by mutations in different domains of the AChR that cause abnormally fast decay of endplate currents and action potentials.

Defects in Postsynaptic Membrane

Defects in the development and maintenance of the endplate have been found in mutations of several postsynaptic genes.

Agrin deficiency or malfunction affects not only AChR clustering and signal transduction but also structural maintenance of the NMJ, which is essential for synapse formation.

LRP4 mutations affect its ability to bind both MuSK and agrin, thus disrupting postsynaptic signal transduction.

MuSK mutations disrupt its function and show extensive remodeling of the endplates. Patients often present with ptosis and respiratory distress at birth and develop weakness in facial, ocular, and limb muscles later.

Dok-7 is an activator of MuSK and many mutations have been identified that inhibit its function and postsynaptic signaling. Patients all demonstrate marked limb-girdle weakness with relative preservation of facial, ocular, and bulbar muscles.

Rapsyn is a protein that anchors the AChR in the postsynaptic membrane and are essential for developing junctional folds and, when mutated, the endplate degenerates. These patients often present in the first year of life, with arthrogryposis and other congenital malformations.

Defects in Glycosylation

Glycosylation affects the solubility, stability, and assembly of peptides. Glycosylated proteins are found at the postsynaptic membrane; thus, NMJ transmission may be compromised by defects in glycosylation. Defects in several glycosylation enzymes were found to cause CMS. On electron microscopy, there are tubular aggregates seen in the sarcoplasmic reticulum, which may be a clue to diagnosis. Defects in GFPT1 result in underdeveloped endplates and suggest hypoglycosylation of postsynaptic proteins such as MuSK, agrin, and dystroglycans. Defects in

DPAGT1 resulted in decrease to 50% of normal of ACh release, postsynaptic ACh response, and AChR concentration.

Other Congenital Myasthenic Syndromes

PREPL deletion syndrome (hypotonia-cystinuria syndrome) results in cystinuria, growth hormone deficiency, muscle weakness, poor feeding, and ptosis. PREPL is essential for filling synaptic vesicles with ACh and thus results in decreased ACh release.

Plectin is a protein that crosslinks intermediate filaments and provides cytoskeletal support. Defects cause a wide variety of syndromes including muscular dystrophy, CMS, and epidermolysis bullosa simplex. In CMS, the junctional folds degenerate with loss of structure and AChR.

Defects in the sodium channel Na1.4 (SCN4A) results in compromised safety margin for NMJ transmission due to fast inactivation and use-dependent inactivation.

Treatment of Congenital Myasthenic Syndromes

Treatment for CMS include cholinergic agonists, drugs which increase the amount of available ACh at the NMJ (pyridostigmine and 3,4-diaminopyridine [3,4-DAP]), open-channel blockers of the AChR ion channel (fluoxetine and quinidine), and β-adrenergic agonists, which stabilize the NMJ and reduce AChR dispersion (salbutamol and ephedrine). Pyridostigmine blocks acetylcholinesterase and thus increases the amount of ACh available for NMJ transmission. 3,4-DAP is a potassium channel blocker on the presynaptic membrane that prolongs the nerve action potential thus increase the release of ACh quanta into the synapse. Both increase the amplitude of the endplate potential and help meet the safety margin for NMJ transmission.

β-Adrenergic agonists are thought to function by stabilizing the NMJ and reducing dispersion of the AChR. Response to treatment is usually over months and even up to a year. Salbutamol and albuterol are the most commonly utilized. Blood pressure should be monitored and laboratory testing for hypokalemia.

Fluoxetine and quinidine are long-lived open-channel blockers of the acetylcholine receptor. These function by keeping the AChR channel in the open state, reducing the opening time of the receptor and is most helpful for the slow-channel syndrome where prolonged channel opening time causes depolarization block (Table 93.7).

TABLE 93.7 Treatment of Congenital Myasthenic Syndromes

Treatment	CMS	Notes
Pyridostigmine 3,4-DAP	ChAT, RAPSN, glycosylation defects, AChR subunit, fast-channel syndrome	**May worsen slow-channel syndrome, COLQ, Dok-7
Salbutamol Albuterol	COLQ, Dok-7, agrin, MuSK, LRP4	Monitor BP and for hypokalemia
Quinidine Fluoxetine	Slow-channel syndrome	**Quinidine-arrhythmias Fluoxetine-may prolong QTc at high doses.

Abbreviations: 3,4-DAP, 3,4-diaminopyridine; AChR, acetylcholine receptor; BP, blood pressure; ChAT, choline acetyltransferase; CMS, congenital myasthenic syndromes; LRP4, LRP4 lipoprotein receptor–related protein 4; MuSK, muscle-specific tyrosine kinase.

DRUG-INDUCED MYASTHENIA GRAVIS

Penicillamine

Until recently, the best example of this condition occurs in patients treated with penicillamine for rheumatoid arthritis, scleroderma, or hepatolenticular degeneration (Wilson disease). The clinical manifestations and AChR antibody titers are similar to those of typical adult MG, but both disappear when drug administration is discontinued. Cases attributed to the anticonvulsant trimethadione have been less thoroughly studied.

Immune Checkpoint Inhibitors

Immune checkpoints are a normal part of the immune system and act to prevent an immune response from being too strong and destroying healthy tissues. Immune checkpoint proteins bind to the surface of T cells and inhibit their function. Two major immune checkpoint proteins are programmed cell death protein 1 (PD-1) and cytotoxic T-lymphocyte–associated protein 4 (CTLA-4). This process can prevent the immune system from destroying cancer cells and thus became a target of investigation for cancer treatment. Since 2011, seven immune checkpoint inhibitors (ICIs) have been approved by the FDA for treatment of cancers: PD-1 inhibitors (pembrolizumab, nivolumab, cemiplimab), programmed cell death-ligand 1 (PD-L1) inhibitors (durvalumab, avelumab, atezolizumab), and cytotoxic T-lymphocyte–associated protein 4 inhibitors (ipilimumab). ICIs were originally developed and approved for metastatic melanoma but are now approved for use in a wide-range of cancers, and their use in treatment is increasing. Despite their promising benefits in treating cancers, serious side effects known as *immune-related adverse events* (irAEs) have developed and can limit treatment. These irAEs can affect numerous different organ systems in the body and cause numerous different neurologic syndromes (thought to affect approximately 1%-3% of patients treated with checkpoint inhibitors), including MG and myositis. Exacerbation of preexisting MG and the development of new-onset MG in patients treated with ICIs has become a well recognized treatment-associated irAE. Clinically, the onset is often acute (within 4 wk of ICI treatment initiation) with rapid deterioration (can be 7 d from MG symptom onset to severe progression), and a majority may have severe muscle weakness with respiratory dysfunction (approximately 45%). AChR antibody titers in patient with prior MG have been shown to increase with ICI treatment, and a significant number were found to have anti-striated antibodies, and many also have elevated creatine kinase. Several cases of concomitant MG and myositis have been reported. Treatment involves cessation of the ICI and aggressive immunotherapy (steroids, IVIG, PE, etc) for MG. There are reports of rechallenge with ICI after recovery from MG in which MG was not precipitated upon rechallenge. Of the ICIs on the market, most have been reported to cause MG and MG/myositis overlap syndromes.

Medications Which may Exacerbate Myasthenia Gravis

Numerous classes of medications can have effects on neuromuscular transmission and thus cause an exacerbation of MG. These include antibiotics (especially aminoglycosides, fluoroquinolones), magnesium and magnesium-containing medications (ie, laxatives, antacids), botulinum toxin, β-blockers and calcium channel blockers, neuromuscular blockers, anesthetics and ICIs.

LAMBERT-EATON MYASTHENIC SYNDROME

Introduction

LEMS is an autoimmune disease of presynaptic NMJ. Antibodies are directed against the P/Q-type voltage-gated calcium channels in peripheral motor nerve terminals (see Fig. 93.1).

Epidemiology

LEMS is rare and found essentially only in adults. A 2017 study of a Veterans Affairs population in the United States confirmed 2.6 cases per 1 million, which is similar to prior studies from the Netherlands. It can be either autoimmune or paraneoplastic. About half of LEMS cases are paraneoplastic, and of these, 80% occur with small cell carcinoma of the lung. The neurologic symptoms almost always precede those of the tumor; the interval may be as long as 5 years. Other tumors have also been implicated, but about 33% of cases are not associated with a tumor. Tumor-free individuals tend to show the HLA-B8 and HLA-DR3 haplotype, which are not found in those with neoplasms.

Pathobiology

The P/Q-type voltage-gated calcium channels on the presynaptic nerve terminal membrane allows the calcium influx in response to nerve impulse, which then triggers ACh quanta release into the synapse, resulting in failure of neuromuscular transmission and muscle weakness. The abnormality of neurotransmission is attributed to inadequate release of ACh from nerve terminals at both nicotinic and muscarinic sites and therefore both neuromuscular weakness and autonomic dysfunction occur in this syndrome. When IgG from affected patients is injected into mice, the number of ACh quanta released by nerve stimulation is reduced, and there is disarray of the active zone particles that can be detected by freeze-fracture ultrastructural analysis.

Purified calcium channel proteins can be directly radiolabeled. An alternative label can be generated by the use of specific ligand, omega-conotoxin, which is prepared from a marine snail (*Conus magus*) and has been used to identify P/Q-type calcium channels in extracts of small cell carcinoma, neuroblastoma, and other neuroendocrine cell lines. A diagnostic test for the autoantibodies is based on radiolabeled preparations, but it is not fully specific. In one series, 92% of 72 patients had a positive reaction. A glial cell nuclear antigen identified in small cell lung carcinoma (SCLC) (a developmental transcription factor) is reactive in 22% of SCLC patients and has been identified in 64% of patients with both LEMS and SCLC but none of those with LEMS alone. This could provide a marker of concurrent SCLC in patients with LEMS. There have been a few positive tests for this antigen in paraneoplastic cerebellar disorders. Some patients have both LEMS and a cerebellar syndrome.

Diagnosis

Clinical Features

LEMS may be suspected in patients with symptoms of proximal limb weakness who have lost knee and ankle jerks and complain of dry mouth or myalgia. Other less common autonomic symptoms include impotence, constipation, and hypohidrosis. LEMS differs clinically from MG because diplopia, dysarthria, dysphagia, and dyspnea are lacking. Autonomic symptoms are more common in LEMS than in MG.

Electrodiagnosis and Laboratory Testing

The disease is defined, and the diagnosis made, by the characteristic incremental response to repetitive nerve stimulation, a pattern that is the opposite of MG. The first evoked potential has an abnormally low amplitude, which decreases even further at low rates of stimulation. At rates greater than 10 Hz, however, there is a marked increase in the amplitude of evoked response (2-20 times the original value) (see Fig. 93.3C). The increment results from facilitation of release of transmitter at high rates of stimulation, which can also be achieved by exercise. At low rates, the number of quanta released per impulse (quantal content) is inadequate to produce endplate potentials that reach threshold. Similar abnormalities are found in preparations exposed to botulinum toxin or to a milieu low in calcium or high in magnesium.

Appropriate search for malignancy should be done in all patients diagnosed with LEMS, including CT chest, and possibly positron emission tomography scan. If initially negative, screening should be repeated in the ensuing years because the LEMS may precede the malignancy.

Some patients with LEMS have ptosis with antibodies to AChR. This combined syndrome may be an example of multiple autoimmune diseases in the same individual.

Management

Treatment is directed to the concomitant tumor in paraneoplastic LEMS. The neuromuscular and autonomic symptoms are treated with drugs that facilitate release of ACh, such as 3,4-DAP and amifampridine. Both improve symptoms in approximately 85% of patients. These two drugs were approved by the FDA in 2018 for the treatment of adults with LEMS (amifampridine) and children aged 6 to 17 years (3,4-DAP) after two phase III clinical trials showed safety and efficacy of 3,4-DAP for LEMS LEVEL 1.[15,16] Seizures may be provoked at high doses and patients with hepatic or renal dysfunction need to be monitored. A combination of pyridostigmine and 3,4-DAP also improves strength and the pyridostigmine can help dry mouth.

Other treatments that may be helpful include PE, IVIG, steroids, and immunosuppressive agents. A small, randomized placebo-controlled crossover trial showed short-term benefit in strength for LEMS patients treated with IVIG, presumably due to the lower levels of circulating antibodies LEVEL 1.[17]

BOTULISM

Epidemiology and Pathobiology

Botulism is a disease in which nearly total paralysis of nicotinic and muscarinic cholinergic transmission is caused by botulinum toxin, which acts on presynaptic mechanisms for release of ACh in response to nerve stimulation. The heavy chain of the toxin mediates binding of the toxin to surface receptors on motor nerve terminals. This allows the toxin molecule to be internalized via endocytosis, and the light chain is then translocated into the cytoplasm. The light chain functions as a zinc-dependent protease that cleaves different components of synaptic vesicles depending on the serotype of the toxin. Botulinum toxin serotypes A and E cleave the SNAP-25 protein; serotype B cleaves synaptotagmin; serotypes B, F and G cleave synaptobrevin. The effect of each of these toxins cleaving different proteins of the synaptic vesicle is to disrupt exocytosis (see Fig. 93.1).

The toxins are produced by spores of clostridial agents. *Clostridium botulinum*, which may contaminate foods grown in soil, produces types A, B, F, and G or in fish, type E; *Clostridium butyricum* produces type E; and *Clostridium barati* produces type F. Intoxication results if contaminated food is inadequately cooked and the spores are not destroyed or if fish are not eviscerated before drying or salt curing. Toxin can be produced in anaerobic wounds that have been contaminated by organisms and spores. Ingestion or inhalation of spores by infants may cause botulism when toxins type A or B are produced in the gastrointestinal tract during periods of constipation. An analogous syndrome occurs in adults with growth of *C botulinum* in the intestine after surgery from gastric achlorhydria or from antibiotic therapy. The toxin does not cause cell death, although it disrupts exocytosis. The effects slowly disappear over several months.

Diagnosis

Clinical Features

Isolated cases in children and adolescents may be thought to be Guillain-Barré syndrome, MG, or even diphtheria. Ptosis has responded to intravenous edrophonium chloride in a few patients, but response to anticholinesterase drugs is neither sufficiently extensive nor sufficiently prolonged to be therapeutic. Infants with botulism are usually younger than 6 months. They show generalized weakness, which is manifested by reduced spontaneous movements, lethargy, poor sucking, and drooling. Sucking and gag reflexes are decreased or absent. There is facial diplegia, ptosis, and ophthalmoparesis.

Laboratory and Electrodiagnostic Testing

Diagnosis is made by the following characteristics: symmetry of signs, dry mouth or absence of saliva, pupillary paralysis, and the characteristic incremental response to repetitive nerve stimulation (see Fig. 93.3C). The Centers for Disease Control and Prevention (with a dedicated emergency 24-h telephone number) or appropriate state laboratories should be notified so that the toxin can be identified in refrigerated samples of serum, stool, or residual food samples. In suspected infantile botulism, feces should be evaluated for the presence of *C botulinum* as well as toxin.

Electrophysiologic evidence of severely disturbed neuromuscular transmission includes an abnormally small single-muscle action potential evoked in response to a supramaximal nerve stimulus. When the synapse is driven by repetitive stimulation at high rates (20-50 Hz), the evoked response is potentiated up to 400% (see Fig. 93.3C). In affected infants, muscle action potentials are unusually brief, of low amplitude, and overly abundant. This is presumably related to involvement of terminal nerve twigs in endings of many motor units. In patients treated for blepharospasm or other movement disorders by intramuscular injections of botulinum toxin, single-fiber EMG shows increased jitter in muscles remote from those injected, and the jitter is maximally increased at low firing rates. These abnormalities are not symptomatic but imply an effect of circulating toxin.

C botulinum toxin is called the *most poisonous poison* (the lethal dose for a mouse is 10^{-12} g/kg body weight). If a patient survives and reaches a hospital, symptoms include dry, sore mouth and throat; blurred vision; diplopia; nausea; and vomiting. Signs include hypohidrosis; total external ophthalmoplegia; and symmetric descending facial, oropharyngeal, limb, and respiratory paralysis. Pupillary paralysis, however, is not invariable. Not all patients are equally affected, suggesting variable toxin intake or variable individual responses. When cases occur in clusters, the diagnosis is usually suspected immediately.

Management

Patients should be treated in intensive care facilities for respiratory care. Specific therapy includes antitoxin (a horse serum product that may cause serum sickness or anaphylaxis), available from the Centers for Disease Control and Prevention, and guanidine hydrochloride, which promotes release of transmitter from residual spared nerve endings but may depress bone marrow. Botulinum immune globulin is given in cases of infant botulism to reduce time on ventilator as well as time in the hospital.

ACKNOWLEDGMENT

The author wishes to recognize the contributions of Lewis P. Rowland (deceased) to previous versions of this chapter.

94 Inflammatory and Autoimmune Myopathies

Rebecca Traub, Kurenai Tanji, and Christina M. Ulane

KEY POINTS

1. Recent developments in understanding of the pathophysiology of inflammatory myopathies have led to a new classification with five main subtypes: dermatomyositis, antisynthetase syndrome and overlap myositis, immune-mediated necrotizing myopathy, sporadic inclusion body myositis, and polymyositis.
2. Most inflammatory myopathies present with symmetrical proximal limb weakness and variable systemic features, whereas inclusion body myositis can have distal and asymmetrical limb weakness.
3. Cancer and interstitial lung disease can be associated with most inflammatory myopathies and should be screened for.
4. Dermatomyositis is an autoimmune microvasculitis affecting skin, muscle, and sometimes lung; the pathologic hallmarks are perifascicular inflammation and necrosis, with both B- and T-cell infiltrates and immunohistochemical staining for myxovirus resistance protein A positive.
5. Antisynthetase syndrome and overlap myositis are often associated with other autoimmune diseases and interstitial lung disease and pathology reveals T cell predominant inflammation.
6. Immune-mediated necrotizing myopathy can be seen in the context of statin use but can also occur in isolation or with other autoimmune diseases.
7. Immune-mediated necrotizing myopathy is clinically more aggressive, and although pathology shows predominant myonecrosis and less inflammation, aggressive immunotherapy with multiple agents is often required.
8. Sporadic inclusion body myositis is distinct in that it is not responsive to immunotherapy and may be a degenerative disease with secondary inflammatory features.

INTRODUCTION

Myopathies, or disorders of skeletal muscle, are due to a variety of hereditary and acquired causes. Myopathies with genetic underpinnings are discussed in Chapters 97 and 99 and throughout Section 19. Acquired myopathies due to systemic disorders and toxins are the subject of Chapter 96. This chapter focuses on acquired inflammatory and autoimmune myopathies. The focus is on prototypical, noninfectious myositis or idiopathic inflammatory myopathies (IIMs): dermatomyositis (DM), antisynthetase syndrome (ASS) and overlap myositis, inclusion body myositis (IBM), polymyositis (PM), and immune-mediated necrotizing myopathy (IMNM). Of note, true PM has become a rarer entity, and diagnosis of exclusion as most patients formerly characterized as having PM would now be categorized under other subtypes. IBM is included here; however, the lack of response to conventional immunotherapies has promoted the idea that it may not belong among the IIMs. IIMs are heterogenous disorders characterized by muscle inflammation, but frequently display other organ involvement, namely skin, lung, and joints. Distinguishing these disorders from hereditary or toxic myopathies is essential for appropriate management of patients with muscle diseases, which may have similar clinical presentations.

The classification and diagnosis of myositis originally developed by Bohan and Peter in 1975 remains widely used to this day (Table 94.1). Numerous additional classification systems have been proposed over the years to take into account clinical, pathologic, and serologic discoveries. Currently, there are five main subtypes of IIMs that are now widely recognized, which will be discussed here: DM, ASS and overlap myositis, IMNM, PM, and IBM. Subtypes of the IIMs can be distinguished based on clinical features, myositis-specific and myositis-associated antibodies, and histopathologic correlates. Treatment is still largely based on expert opinion, but certain therapies have been shown effective in studies for particular subtypes.

TABLE 94.1 Bohan and Peter Criteria for Myositis[a]

Criterion	Description
Symmetric proximal weakness (over weeks to months)	Neck flexors, limb-girdle musculature
Consistent muscle biopsy findings	Necrosis, regeneration, phagocytosis, atrophy, mononuclear cell infiltrates
Elevated muscle enzymes	Creatine kinase, aldolase, transaminases, lactate dehydrogenase
Electromyographic evidence for myopathy	Muscle fiber irritability (positive sharp waves, fibrillations), short duration, small amplitude, polyphasic motor unit potentials, with spontaneous bizarre high-frequency discharges
Characteristic skin rash	Gottron sign, Gottron papules, heliotrope

[a]Definite polymyositis: four criteria; definite dermatomyositis: three or four criteria plus rash; possible polymyositis: two criteria; possible dermatomyositis: one criterion plus rash.

DERMATOMYOSITIS

Introduction

DM classically consists of characteristic rash and myositis; amyopathic or hypomyopathic forms have also been described.

Epidemiology

DM is rare and exact epidemiologic data is lacking. A recent systematic review and meta-analysis estimates an incidence of approximately 7.98 cases per million per year and a prevalence of 14 per 100,000 (range 2.4-33.8 per 100,000) for all inflammatory myopathies.

DM occurs in all decades of life, with peaks of incidence before puberty and at about age 40 years. In young adults, women are more likely to be affected. Familial cases are rare. Adult cases are associated with an increased risk of malignant neoplasms; most often ovarian, lung, or breast cancer, although others such as nasopharyngeal carcinoma have been reported. Most studies report 15% to 25% of adult DM is associated with malignancy.

Juvenile DM is extremely rare, with estimated incidence of 2 to 5 per 1 million children per year younger than 16 years of age. It much more common in girls than boys (5:1) and essentially never associated with malignancy.

Pathobiology

DM is thought to be an autoimmune disease with vasculopathy of muscle and skin. The antigenic target appears to be the endothelium of intramuscular microvessels, activating complement pathways to cause vascular injury. The loss of capillaries is thought to cause muscle ischemia resulting in myofiber injury and loss. Lymphocytic infiltrates are composed of both B and T cells, as contrasted to the T-cell–predominant inflammatory process of PM and IBM.

Clinical Features

The typical clinical presentation of DM is a combination of proximal limb weakness with characteristic skin findings (Fig. 94.1). The rash may precede weakness by several weeks, but weakness alone is almost never the first symptom. Sometimes, the rash is so typical that the diagnosis can be made even without evidence of myopathy (amyopathic DM). In other cases, weakness may not be evident, but there is electrophysiologic, pathologic, or serum creatine kinase (CK) evidence of myopathy.

Weakness in DM primarily affects the proximal muscles in the arms and legs and may be accompanied by discomfort (myalgias) and tenderness. Patients often describe difficulty going up stairs, standing from a seated position, and lifting arms above the head. Cranial muscles may be involved, causing facial weakness, dysphagia, and esophageal involvement. Neck weakness may occur, causing head drop. Sensation is preserved and reflexes are lost only when the myopathy is severe.

The typical rash is on the face, often on the upper eyelids as a purplish discoloration with edema (heliotrope rash). An erythematous macular rash may be found on the face, neck and chest (V-sign), and upper back (shawl sign). The initial redness may be replaced later by brownish pigmentation. Gottron sign is denoted by red-purple scaly macules on the extensor surfaces of finger joints.

FIGURE 49.1 Common violaceous rashes identified in dermatomyositis. **A:** Linear extensor erythema on the dorsum of the hand. **B:** Heliotrope rash in a periorbital distribution. **C:** Shawl sign over a patient's back. **D:** Holster sign, as seen over the lateral hip.

Subcutaneous calcifications can occur, more often in chronic cases and in pediatric DM. These calcifications may erode through the skin and cause ulceration and secondary infection.

Interstitial lung disease (ILD) may accompany DM, but mainly with anti-melanoma differentiation-associated gene 5 (MDA5) antibodies in which case it is severe. Patients should be questioned about respiratory symptoms and referred for pulmonary evaluation when appropriate. Cardiac involvement can occur, so clinical history should include questions of chest pain, palpitations, and syncope, and cardiac screening is advised.

Juvenile DM presents with a similar rash and proximal weakness.

Diagnosis

DM is a clinical diagnosis aided by muscle and skin biopsy (see the "Muscle Pathology" section later in this chapter), but more recently subtypes can be diagnosed based on myositis-specific antibodies (see **Table 94.1**). There should be elevations in muscle enzymes, including CK and aldolase. Approximately 70% of DM patients will have DM-specific autoantibodies. The anti–Mi-2 antibody is associated with classic DM with significant skin involvement and proximal weakness. Antibodies against nuclear matrix protein (NXP)-2 more often have both proximal and distal weakness, edema, dysphagia, and calcinosis. Patients with either anti–NXP-2 or anti–transcription intermediary factor (TIF)-1 are at higher risk for malignancy. Muscle is moderately involved in patients with anti–Mi-2 and anti–NXP-2 antibodies, whereas there is only mild or no muscle involvement in patients with anti–TIF-1, anti-small ubiquitin-like modifier activating enzyme (SAE), anti-MDA5 antibodies, and seronegative DM. Severe lung and skin involvement is seen in DM with anti-MDA5 antibodies (**Table 94.2**).

Electrodiagnostic testing typically demonstrates normal nerve conduction studies with myopathic findings on electromyogram (EMG) with fibrillations, positive sharp waves, complex repetitive discharges, and sometimes myotonia or waning discharges, suggesting an inflammatory process. Magnetic resonance imaging (MRI) of the muscles can be used to look for evidence of inflammation and direct a target for muscle biopsy.

The differential diagnosis for DM includes the other immune-mediated myopathies, hereditary muscular dystrophies, and toxic myopathies. Clinical features, electrodiagnostic findings, muscle pathology, and genetic testing can help distinguish these entities (see **Table 94.4**).

Once the diagnosis of DM is suspected, testing should include evaluation for underlying malignancy and associated pulmonary fibrosis. Computed tomography of the chest, abdomen, and pelvis is usually sufficient, with the addition of pelvic ultrasound and mammogram in woman, although positron emission tomography may be indicated in some cases.

TABLE 94.2 Dermatomyositis-Specific Antibodies

Autoantibody	Clinical Features
Anti–Mi-2	Moderate muscle involvement, classic skin rash
Anti–NXP-2	Moderate muscle involvement (proximal and distal), classic skin rash, calcinosis, edema, dysphagia, increased risk of malignancy
Anti–TIF-1	Mild muscle involvement, classic skin rash, strong association with malignancy (may include amyopathic DM)
Anti-MDA5	Minimal or no muscle involvement, severe skin involvement, severe ILD
Anti-SAE	Mild muscle involvement with classic skin rash
Seronegative DM	Mild muscle involvement, moderate skin involvement

Abbreviations: DM, dermatomyositis; ILD, interstitial lung disease; MDA5, melanoma differentiation-associated gene 5; NXP-2, nuclear matrix protein-2; SAE, small ubiquitin-like modifier activating enzyme; TIF-1, transcription intermediary factor-1.

Management

Treatment for DM and the other IIMs is similar. The initial treatment for DM is prednisone, typically starting with high dose (60 mg daily or higher) and then tapering slowly over months in conjunction with the addition of steroid-sparing immunomodulating therapies.

The usual first-line steroid-sparing agent used in inflammatory myopathies is methotrexate. Methotrexate can be given orally or subcutaneously (start 7.5 mg/wk, titrate up by 2.5 mg weekly to goal of 10-20 mg weekly; given with folic acid 1 mg daily) with close monitoring of cell counts, hepatic function, and renal function. Because of the risk of pulmonary fibrosis as a complication of methotrexate therapy, it should be avoided in patients with ASS if possible. Another first- or second-line steroid-sparing agent is azathioprine LEVEL 1.[1,2] Azathioprine is started at a low dose (50 mg daily) and slowly increased (goal of 2-3 mg/kg/d), with monitoring of cell counts and hepatic function. Patients should be tested for thiopurine S-methyltransferase enzyme deficiency prior to initiating azathioprine because this can help predict patients at high risk for bone marrow toxicity. In patients with myositis refractory to these agents or with intolerable side effects, second-line options include rituximab (1,000 mg intravenous on days 1 and 15 may be repeated every 24 wk) and intravenous immunoglobulin (IVIG) (doses vary, typically 1-2 g/kg intravenous every 2-4 wk). Rituximab, a monoclonal anti-CD20 antibody, when studied for treatment of DM and PM in a randomized controlled trial, failed to meet the primary outcome measure, but clinical improvement and a significant reduction in steroid dose was seen in all patients receiving the treatment LEVEL 1.[3] A randomized controlled trial of IVIG in treatment-resistant cases of DM showed it to be effective in 9 of 12 cases LEVEL 1.[4] The American Academy of Neurology 2012 guidelines recommend IVIG as a possibly effective therapy for refractory DM. Other medications occasionally used for refractory cases include cyclosporine (starting 2.5 mg/kg daily divided twice a day), tacrolimus (0.075 mg/kg/d divided twice a day), mycophenolate mofetil (starting 500-1,000 mg daily), and cyclophosphamide (doses starting at 300 mg/m^2 every 4 wk). Many of these second- and third-line immunosuppressive medications have significant toxicities and side effects and should be prescribed by specialists familiar with their use. For refractory disease, additional biologic agents that may be considered include abatacept and tocilizumab.

Treatment must include management of associated systemic manifestations, with close coordination between rheumatology, neurology, pulmonology, cardiology, and oncology when appropriate.

Physical therapy, occupational therapy, and low-intensity exercise are generally recommended for all patients with inflammatory myopathies to prevent deconditioning, help with gait training, and improve muscle strength.

Treatment of juvenile DM is similar, and high-dose daily oral prednisone or pulsed intravenous methylprednisolone is considered the gold standard and must be initiated promptly to prevent significant morbidity and mortality. Other steroid-sparing immunosuppressives in those who do not respond to or cannot tolerate steroids including methotrexate and cyclosporine may be used.

ANTISYNTHETASE SYNDROME AND OVERLAP MYOSITIS

Introduction

Overlap myositis and ASS are types of myopathies associated with other autoimmune diseases such as systemic lupus erythematosus (SLE), rheumatoid arthritis, Sjögren syndrome or systemic sclerosis. In terms of the myopathic weakness, the presentation and treatment is similar to DM, absent the typical dermatologic findings of the latter. Overlap myositis and ASS are much more likely to have significant lung involvement compared to DM. Pathologically, these are distinct entities from DM. Treatment is similar to that for DM, but distinguishing these entities is important for monitoring of other organ involvement and cancer risk.

Epidemiology

IIMs as a whole are reported with a prevalence of approximately 14 in 100,000. The percentage of inflammatory myopathies identified as PM vary widely from 2% to over 50% in different series.

Pathobiology

The ASS is most representative of this category and the autoantibodies target the aminoacyl transfer RNA synthetases. It is considered an autoimmune disease of disordered cellular immunity (in contrast to the presumed humoral abnormalities of DM). The antigenic target is not known; however, and the nature of the immunologic aberration is uncertain. Although there is some increased risk of malignancy in association with ASS and overlap myositis, the association is not as high as that seen in DM.

Clinical Features

The myopathy of the overlap myositis and ASS is nonspecific and typically affects proximal limb muscles, similar to DM; patients have difficulty climbing stairs or rising from low seats, lifting packages or dishes, or working with the arms overhead. Weakness of neck muscles may result in head drop. Typically, cranial muscles are spared, although dysphagia can occur when the disease is severe. Respiratory muscles are only rarely affected. Pain, or myalgias, may be present, but sensory symptoms are otherwise absent.

Systemic features associated with overlap myositis and ASS include ILD, arthritis, Raynaud syndrome, fever, and mechanic's hands (hyperkeratotic lesions, which appear as dusky discoloration of the knuckles). Some have rashes similar to those seen in DM. Patients with anti–Jo-1 antibodies have more severe and frequent weakness, whereas anti–PL-12 antibodies are associated with ILD but no muscle involvement, and the most severe ILD is seen in anti–PL-7 and anti–PL-12.

Diagnosis

The diagnosis of ASS and overlap myositis is made in the appropriate clinical setting with a combination of autoantibody testing, electrodiagnostic, and muscle biopsy findings (see "Muscle Pathology" section for the latter). The differential diagnosis includes other inflammatory myopathies, toxic myopathies, and hereditary muscle diseases (see Table 94.4). Motor neuron disease (amyotrophic lateral sclerosis) may be included in the differential diagnosis because of modestly elevated CK levels, although the clinical and electrodiagnostic findings are distinctive in amyotrophic lateral sclerosis.

The electrodiagnostic findings of ASS and overlap myositis are indistinguishable from those in DM. Nerve conduction studies are normal except in the case of severe myopathy, in which case motor compound motor action potential (CMAP) amplitudes may be reduced. Needle EMG shows fibrillations, complex repetitive discharges, and other "inflammatory" findings in combination with myopathic motor unit potentials, which are low amplitude, short duration, polyphasic, and with early recruitment.

Lab testing will demonstrate elevations in serum CK and aldolase as markers of muscle inflammation. Autoantibodies present in ASS and overlap myositis help distinguish subtypes (Table 94.3). Antibody testing may be suggestive of an underlying rheumatologic disorder in overlap myositis, including positive antinuclear antibody or scleroderma antibodies.

As in DM, muscle MRI is sometimes useful in targeting muscle biopsy.

Differential diagnosis is similar to the other inflammatory myopathies (Table 94.4).

Management

Treatment of overlap myositis and ASS is similar to DM. First-line and initial treatment is with high-dose steroids, typically prednisone, with the same consideration for steroid-sparing agents and options for refractory disease as elaborated in the DM treatment section earlier.

TABLE 94.3 Antisynthetase Syndrome and Overlap Myositis Antibodies

Autoantibody	Clinical Features
Antisynthetase Antibodies	
Anti–Jo-1	Moderate muscle involvement, progressive lung involvement
Anti–PL-7	Moderate muscle involvement with severe lung involvement
Anti–PL-12	Mild muscle involvement and severe lung involvement
Overlap Myositis Antibodies	
Anti-PM/Scl	Mild muscle, lung, and skin involvement with features of scleroderma
Anti-Ku	Mild muscle and lung involvement
Anti–U1-RNP	Mild muscle involvement, features of scleroderma and SLE, possible renal involvement

Abbreviations: SLE, systemic lupus erythematosus; U1-RNP, U1 ribonucleoprotein.

TABLE 94.4 Differential Diagnosis of Inflammatory Myopathies

Mimic	Differentiating Characteristics
Dermatomyositis	Associated characteristic rash, specific pathologic findings on muscle biopsy, myositis-specific antibodies
Antisynthetase syndrome	Significant lung involvement, specific muscle pathology, myositis-specific antibodies
Overlap myositis	Associated rheumatologic diagnosis (eg, lupus, rheumatoid arthritis)
Immune-mediated necrotizing myopathy	Specific pathologic findings on muscle biopsy, drug/statin exposure, more resistant to immunosuppressant therapy, specific antibodies
Inclusion body myositis	Slower progression, older age of onset, male precominance, asymmetric and distinct distribution of muscle weakness, specific pathologic findings on muscle biopsy, lack of response to immunosuppressants
Muscular dystrophy	Age of onset, slower progression, family history, specific pathologic findings on muscle biopsy, genetic testing, lack of response to immunosuppressants
Metabolic myopathy	Age of onset, slower progression, family history, pathology, genetic testing, lack of response to immunosuppressants
Fibromyalgia	Prominent pain, no weakness, normal EMG and muscle biopsy
Polymyalgia rheumatica	High ESR/CRP, normal CK, normal EMG

Abbreviations: CK, creatine kinase; CRP, C-reactive protein; EMG, electromyogram; ESR, erythrocyte sedimentation rate.

SPORADIC INCLUSION BODY MYOSITIS

Introduction

IBM is still considered an inflammatory myopathy, although it is quite distinct in clinical features and treatment response. In addition, IBM exhibits unique pathologic features, suggesting that IBM may have dual aspects of inflammatory and degenerative muscle diseases.

Epidemiology

The prevalence of IBM varies from 4.9 per million in the Netherlands to 71 per million in Olmstead County, Minnesota. Both prevalence and incidence increase if restricted to age older than 50 years. There is a 2:1 to 3:1 male predominance, unlike most autoimmune disorders with female predominance. Up to 15% will have an associated autoimmune disease such as lupus, Sjögren syndrome, thrombocytopenia, or sarcoidosis.

Pathobiology

The cause of IBM is unknown, but it is thought to be both autoimmune and neurodegenerative. The inflammatory response in the muscle and acquired nature suggest an immune etiology (see "Muscle Pathology" section). A novel autoantibody has been identified from sera of 50% of patients with IBM that recognized a 43 kDa muscle protein, the cytosolic 5′-nucleotidase 1A (encoded by *NT5C1A*).

Poor responsiveness to immunotherapy suggests a degenerative component of the disease. Histologically, protein aggregates are found in the vacuolated muscle fibers of IBM that are not typically seen in other inflammatory myopathies. These aggregates, which are thought to be accumulation of misfolded proteins, share similar components to those found in other neurodegenerative diseases (see "Muscle Pathology" section).

In contrast to sporadic IBM, *hereditary inclusion body myopathy*, which shares some clinical features and pathologic features with sporadic IBM, is not immune mediated. These genetic disorders are caused by mutations in a number of genes, most often *GNE* and *VCP*, but other genes have been implicated.

Clinical Features

The clinical symptoms of IBM, in its classic form, are distinct from other inflammatory myopathies in the distribution and time course of weakness. The onset of weakness is typically slow, with very gradual progression over the course of years. Many patients will have symptoms for years before diagnosis is established. Muscles first affected are usually proximal legs, with predilection for the quadriceps muscle group, as opposed to other myopathies affecting proximal muscles, which typically have more hip flexor involvement. In the arms, distal muscles tend to be first and more severely affected, with prominent involvement of the finger and wrist flexors in the forearm. Atrophy is often greater than is seen in other inflammatory myopathies and is often asymmetric. Pronounced atrophy and weakness, which can be asymmetric distinguishes IBM from other types of myositis, and is cause for diagnostic confusion with motor neuron disease. Muscle pain (myalgia) is present in approximately 40% of patients. Neck muscles are often involved and can lead to head drop. Dysphagia occurs in half or more of patients, making it a more common symptom in IBM than in other inflammatory myopathies and may be the initial symptom. Rarely, there is involvement of respiratory muscles. Prognosis is for slow progression over years, typically leading to use of wheelchair. Death may occur as complication of respiratory infection or aspiration, but this may be 10 or more years after symptoms begin.

Diagnosis

The diagnosis of IBM is often suspected based on history and physical exam findings, supported by electrodiagnostic studies, but relying on muscle pathology for confirmation (see "Muscle Pathology" section). Lab testing shows mild elevations in CK, up to 15 times the upper limit of normal but may be normal. Antibodies recognizing cytosolic 5′-nucleotidase 1A are found in around 50% of patients with IBM, but up to 5% to 10% of patients with other types of inflammatory myositis and in up to 20% of patients with SLE or Sjögren syndrome. There should be no elevation in erythrocyte sedimentation rate or other inflammatory markers, although there are reports of an association with antinuclear antibody and Sjögren antibodies. Testing should include antibodies for systemic rheumatologic disorders and myositis-specific antibodies.

TABLE 94.5 Differential Diagnosis for Inclusion Body Myositis

Dermatomyositis	Associated skin findings Muscle pathology
Antisynthetase syndrome, overlap myositis, polymyositis	Associated autoantibodies Muscle pathology
Hereditary distal myopathies	Family history Early age of onset Genetic testing
Drug-induced (toxic) myopathies	History of toxic or medication exposure
Motor neuron disease	Upper motor neuron findings Electrodiagnostic testing Muscle biopsy—neurogenic changes
Myasthenia gravis	Ocular and prominent bulbar symptoms Acetylcholine receptor or muscle-specific kinase antibodies Abnormal repetitive stimulation Response to immunotherapy

Electrodiagnostic studies show primarily a myopathic pattern with inflammatory features, similar to that seen in DM and PM. There are fibrillations and abnormal spontaneous activity consistent with an inflammatory process, with short duration and low-amplitude motor unit potentials and early recruitment. In some patients with IBM, however, there is a mixed electrodiagnostic picture, with both short duration and long duration motor unit potentials. These mixed findings on EMG in combination with normal sensory responses can make the diagnosis more challenging and occasionally leads to the misdiagnosis of motor neuron disease in patients with IBM.

Muscle MRI is increasingly being used for diagnosis in inflammatory myopathies, and in IBM, it will show atrophy and/or fatty replacement of muscle with predominant involvement of the anterior thigh muscles.

Given the unique features of IBM, there is a somewhat different differential diagnosis to be considered (**Table 94.5**). There have been a number of diagnostic criteria used to establish the definite or probable diagnosis of IBM for clinical and research use. The most recent of these is the criteria defined in the European Neuromuscular Center workshop in 2011 (Table 94.6).

Management

IBM is notorious for being refractory to the treatments that are effective for other inflammatory myopathies. In some patients, there is an initial response to corticosteroids; however, all will eventually become refractory. Other immunosuppressive agents have not proven to alter the natural course of IBM. A randomized controlled trial of methotrexate showed improved CK levels but no effect on strength. Randomized controlled trials of IVIG with and without steroids also have not shown significant benefits for patients with IBM. Two randomized controlled pilot studies by the Muscle Study Group did not show any benefit for IBM patients treated with interferon. Despite negative trials, some neuromuscular specialists will treat patients with IBM with prednisone, steroid-sparing agents, such as methotrexate or azathioprine, or IVIG on a trial basis based on the observation that a small subset of patients appear to improve or stabilize with regard to muscle strength with treatment, but whether to offer immunotherapy is a controversial topic.

Based on the pathobiologic findings of protein aggregation suggesting a degenerative physiology, several treatments targeting these pathways have been tried. Arimoclomol, which prolongs the activity of heat shock proteins, which in turn prevents protein aggregation, is currently being investigated in a phase II/III trial. Inhibition of myostatin (which is itself an inhibitor of skeletal muscle development) and modulation

TABLE 94.6 Diagnostic Criteria for Inclusion Body Myositis From the European Neuromuscular Center Workshop, 2011[a]

Classification	Clinical Features	Pathologic Features
Clinicopathologically defined IBM	Duration over 12 mo Age at onset older than 45 y Quadriceps weakness greater than hip flexor weakness and/or finger flexor weakness greater than shoulder abductor weakness Serum CK not greater than 15× the upper limit of normal	Endomysial inflammation and rimmed vacuoles and protein accumulation (amyloid or other proteins) Or Filaments 15-18 nm
Clinically defined IBM		One or more of the following: Endomysial inflammation Or increased MHC-1 staining Or rimmed vacuoles Or protein accumulation (amyloid or other proteins) Or filaments 15-18 nm
Probable IBM		One or more of the following: Endomysial exudate Or increased MHC-1 staining Or rimmed vacuoles Or protein accumulation (amyloid or other proteins) Or filaments 15-18 nm

Abbreviations: CK, creatine kinase; IBM, inclusion body myositis; MHC-1, major histocompatibility complex-1.

[a]Adapted from Dimachkie M, Barohn R. Inclusion body myositis. *Neurol Clin*. 2014;32:629-646 and Machado P, Brady S, Hanna MG. Update in inclusion body myositis. *Curr Opin Rheumatol*. 2013;25(6):763-771.

of autophagy are other degenerative pathways under investigation as treatment options.

Given the limited, if any, benefit with immunomodulating therapy for IBM, treatment should focus on symptomatic and supportive therapies to improve quality of life. Low-intensity physical therapy can help with strength and mobility. Falls prevention and gait training are important for preventing complications of worsening weakness. Speech therapy can help in managing dysphagia and preventing aspiration.

IMMUNE-MEDIATED NECROTIZING MYOPATHY

Introduction

IMNM is a distinct type of immune-mediated myopathy that shows on biopsy various degree of myofiber necrosis associated with little or no inflammatory response except for myophagocytosis. IMNM may occur in isolation (with or without anti–signal recognition particle [SRP] antibodies) or in association with statin use (with anti–3-hydroxy-3-methylglutaryl-coenzyme A reductase [HMGCR] antibodies) with certain connective tissue disorders and possibly with malignancies.

Epidemiology

Cases of IMNM in the context of statin use were reported initially in the 1980s, and subsequent case series describe myopathy that progress after statin cessation, with features on biopsy of IMNM and response to immunosuppressant medication. The exact incidence of IMNM is unclear. However, 21% of IMNM is associated with SLE, and in patients with anti-SRP antibodies, most are female, with an average age of onset of 45 years, 65% have comorbid hypertension, 23% have diabetes mellitus, and up to 37% will have ILD. One-third of IMNM cases do not have any myositis-specific antibodies, and these are most often associated with SLE and systemic scleroderma.

Pathobiology

IMNM is characterized by muscle biopsies showing necrosis and degeneration but without the typical inflammatory cell infiltrate seen in DM and PM, despite its autoimmune physiology.

In the case of the statins, there is increased expression of HMGCR on regenerating muscle fibers, which likely triggers and immune response and the subsequent development of anti-HMGCR antibodies. This upregulation persists even after statins have been discontinued, which is presumably why the symptoms continue and even progress after the statin is discontinued. Whether these antibodies are pathogenic or an associated finding is unknown, especially as the target is an intracellular protein. HMGCR is the rate-limiting enzyme in cholesterol synthesis and is the target of statin medications.

Beginning in 1986, antibodies recognizing the SRP on the endoplasmic reticulum membrane were found in association with myopathy. It is also unclear if this antibody is pathogenic because it is too intracellular. However, titers of anti-SRP antibodies and serum CK are found to correlate with one another during treatment.

Clinical Features

Similar to other types of myositis, patients with IMNM present with symmetric proximal weakness over the course of weeks to months. However, in patients with anti-SRP antibodies, the onset may be acute and severe, and 66% to 80% of this group will have myalgias. Anti-SRP myopathy patients can have dyspnea (50%), which may be due to either neuromuscular weakness or lung involvement (13%-22%). Symptoms in statin-related cases can occur at any time in treatment (2 mo to 3 y) but on average, after 3 years of treatment. Symptoms continue or even worsen with cessation of statin and myalgias are a prominent feature (75%). Less commonly, patients can present with HMGCR-positive myopathy in the absence of statin exposure. There are pediatric forms of IMNM, which can mimic muscular dystrophies and must be considered in the differential diagnosis.

Diagnosis

As in other inflammatory myopathies, IMNM is diagnosed with a combination of clinical, lab, and electrodiagnostic features but often relying on muscle pathology to confirm diagnosis (see "Muscle Pathology" section) (Table 94.7).

Serum CK levels are often extremely elevated, usually more than 5,000 U/mL, as in other inflammatory myopathies. Serum can be tested for the presence of anti-SRP and anti-HMGCR antibodies, which are extremely helpful in each case. Patients with anti-SRP myopathy typically do not have any other myositis-specific antibodies. Patients with non-IMNM statin-induced myotoxicity do not have anti-HMGCR antibodies. Anti-SRP antibodies and anti-HMGCR antibodies around found in approximately two-thirds of patients with IMNM. Anti-HMGCR antibodies have been found in patients without prior statin exposure.

Electrodiagnostic testing shows findings similar to that seen in PM and DM with normal nerve conduction studies, unless weakness is severe, in which case CMAP amplitudes may be reduced. There is abnormal spontaneous activity, with fibrillations and other irritable features. Motor unit potentials are myopathic, with short duration and low amplitude, and recruitment is early.

Muscle MRI shows findings similar to other inflammatory myopathies, with muscle edema, atrophy, and fatty replacement. MRI is sometimes helpful in targeting muscle biopsy.

Differential diagnosis is similar to the other inflammatory myopathies (see Table 94.4).

TABLE 94.7 Immune-Mediated Necrotizing Myositis Antibodies

Antibodies in Immune-Mediated Necrotizing Myopathy	
Anti-SRP	Severe muscle involvement with dysphagia, mild lung involvement
Anti-HMGCR	Severe muscle involvement, can be associated with statin exposure
Seronegative immune-mediated necrotizing myopathy	Associated with cancer

Abbreviations: HMGCR, 3-hydroxy-3-methylglutaryl-coenzyme A reductase; SRP, signal recognition particle.

Management

Treatment of IMNM relies on both discontinuing any toxic trigger for the disease process (ie, stopping statins) when implicated. Although typical statin-induced myopathy will improve after discontinuation of the medication, the course of IMNM is of worsening weakness despite stopping the triggering medication. Immunosuppressive treatment is necessary to address the underlying autoimmune pathophysiology in IMNM. Most patients respond to corticosteroids. Other steroid-sparing agents, which have been used with success, include methotrexate, azathioprine, mycophenolate mofetil, rituximab, and IVIG.

POLYMYOSITIS

With the advancement of the understanding of the different autoantibodies and clinical syndromes associated with myositis, most cases of PM can now be classified as having ASS, IBM, or one of the other types of defined myositis. True PM is likely rare and is a diagnosis of exclusion of other types of myositis.

MUSCLE PATHOLOGY

Dermatomyositis

Muscle biopsy in DM shows perimysial, and particularly perivascular, inflammation often composed of a mixed population including macrophages, $CD4^+$ and $CD8^+$ T cells, B lymphocytes, and plasmacytoid dendritic cells. The extent and the degree of inflammation, however, can vary greatly from patient to patient. Except in cases of amyopathic DM, necrotic/degenerative or regenerating fibers are found across the biopsy sections or in a perifascicular pattern. The endomysial capillary density may be significantly reduced. Immunohistochemically, major histocompatibility complex (MHC) class I immunoreactivity is ubiquitous or with a perifascicular predominance, and there is variable MHC class II expression. Immune complexes containing immunoglobulin G, immunoglobulin M, and complement, especially the membrane attack complex (MAC) can be found deposited in the microvessels. In conjunction with the discovery of the distinct effect of interferon type 1 on the microvasculature and muscle in DM, the recognition of sarcoplasmic immunohistochemical staining with the antibody against myxovirus resistance protein A, a key mediator of the interferon-induced antiviral response, has been found to be useful for distinction between DM and ASS (including anti–Jo-1 myopathy). Ultrastructurally, endothelial cells of affected microvessels may show necrosis, swelling, or reactive/degenerative changes. Reactive/degenerative endothelial cells may exhibit tubuloreticular structures that appear closely related to endoplasmic reticulum and are thought to reflect interferon type 1 exposure (Fig. 94.2).

Antisynthetase Syndrome

Antisyntetase syndromes such as anti–Jo-1, anti-OJ, and anti–PL-7–associated myopathy can show similar histologic features to those in DM such as perifascicular patterns of myocyte injury and perimysial inflammation. $CD8^+$ cytotoxic T cells can be more abundant in ASS than in DM, and plasma cells are seen. In typical cases, interstitial connective tissue is markedly fragmented, and perimysial staining of alkaline phosphatase is observed. Immunohistochemically, besides MHC class I positivity, MHC class II is often expressed in a unique perifascicular fashion, and sarcolemmal staining of MAC is seen also among nonnecrotic perifascicular fibers. Unlike DM, immunoreactions of myxovirus resistance protein A antibody are generally absent. Ultrastructurally, nuclear actin aggregation has been reported as a hallmark of ASS.

Polymyositis and Inclusion Body Myositis

PM and IBM histologically share certain features including fiber necrosis and regeneration, and inflammatory infiltration mainly in the endomysium, predominantly consisting of T cells with a large subset of $CD8^+$ cytotoxic cells and macrophages/histiocytes. Occasionally, cytotoxic T cells invading into nonnecrotic appearing sarcoplasm can be captured using immunohistochemical staining for CD8. In IBM, myeloid dendritic cells and plasma cells also appear in the inflammatory infiltrates. Typically, PM and IBM immunohistochemically reveal ubiquitous MHC class I upregulation, whereas often in IBM, patchy or scattered MHC class II expression is observed as well. It is noted that IBM tends to show on biopsy a greater degree of chronic myopathic histoarchitectural changes than PM: markedly increased fiber size variation and endomysial fibrosis may

FIGURE 94.3 Muscle pathology in polymyositis. **A:** Endomysial lymphocytic infiltration *(arrows)* (hematoxylin and eosin stain, ×200 magnification). **B:** Cytotoxic T-cell infiltrate invading myofibers *(arrows)* (immunohistochemical staining for CD8, ×400 magnification).

be observed along with amyloid-laden rimmed vacuole formation. Often, mitochondrial abnormalities are recognized by ragged red and/or cytochrome C oxidase deficient fibers. Intravacuolar amyloid deposition can be well visualized by the fluorescence microscopic examination using rhodamine. The scientific premise of intracellular protein aggregates and faulty proteostasis in IBM has prompted supplemental immunostaining using the antibodies against, for example, β-amyloid, phosphorylated tau, TAR DNA–binding protein 43, ubiquitin, and p62. As no single protein is, however, proven to be solely pathogenic for vacuole formation in IBM, the detection of p62 (a marker of autophagy) immunoreactivity, combined with MHC class I immunoexpression and endomysial T-cell infiltration, are thought to be most informative to establish the morphologic diagnosis of IBM with high specificity and sensitivity (Figs. 94.3 and 94.4).

Immune-Mediated (Autoimmune) Necrotizing Myopathy

IMNM shows scattered necrotic myofibers associated with phagocyte (macrophage) infiltration. Typically, there is little T-lymphocytic infiltration; yet, this may be seen in a subset of cases. In severe cases, especially in younger patients, the disease may progress and become chronic, in which case the muscle biopsy may reveal similar features to those of muscular dystrophy. Immunohistochemically, MHC class I is variably expressed on nonnecrotic/nonregenerating fibers, and MAC deposition can occur on the sarcolemma of nonnecrotic fibers. Morphologic features on muscle biopsy cannot further subclassify the type of IMNM; therefore, serologic testing is required to distinguish antibody-associated IMNM such as anti-SRP and anti-HMG IMNM from seronegative cases (Fig. 94.5).

95 Critical Illness Myopathy and Neuropathy

Ahmad Riad Ramadan, Michio Hirano, and Louis H. Weimer

KEY POINTS

1. Critical illness myopathy (CIM) and critical illness polyneuropathy (CIP) are among the most common causes of intensive care unit–acquired weakness and failure to wean patients from mechanical ventilation.
2. The main risk factors for CIM are nondepolarizing neuromuscular blocking agents and corticosteroids use. For CIP, they are sepsis and multiorgan failure.
3. Loss of thick filaments seen on electron microscopy is a hallmark of CIM. Increased nerve microvasculature permeability has been linked to CIP.
4. Intensive insulin therapy (target blood glucose 80-110 mg/dL) has been shown to reduce the incidence of CIP and CIM.
5. Limiting use of corticosteroids and paralytics, treatment of sepsis, and early physical therapy are cornerstones of the treatment of CIP and CIM.
6. Patients with CIM tend to have a faster and more complete recovery than patients with CIP.

INTRODUCTION

Although critically ill individuals in intensive care units (ICUs) are typically weak due to their severe medical illnesses, a subgroup of patients develops critical illness myopathy (CIM), critical illness polyneuropathy (CIP), or both. The first case of acute quadriplegic myopathy (later renamed CIM) was reported in 1977 by MacFarlane and Rosenthal in a 24-year-old woman who received high-dose corticosteroids for status asthmaticus. In 1984, Bolton and colleagues described five critically ill patients with sepsis and multiorgan failure who developed severe sensorimotor peripheral neuropathies. Since then, hundreds of patients with CIM and CIP have been reported. Together, these disease entities represent two of the most common etiologies of failure to liberate patients from mechanical ventilation in the ICU.

EPIDEMIOLOGY

Although incidence rates of CIM and CIP vary in reported series based on patient populations and detection methods, the disorders appear frequently common in the ICU setting. In one report, about 25% of patients in the ICU developed weakness, whereas electrophysiologic studies have detected neuromuscular abnormalities in up to 84% of patients. Among patients with sepsis or systemic inflammatory response syndrome, the incidence has been estimated to be 70% and virtually 100% in patients with septic shock or sepsis plus coma. In one study, up to a third of all patients receiving mechanical ventilation for at least 4 to 7 days manifested signs of CIP/CIM. In most case series, the incidence of CIM has been greater than CIP; however, some patients manifest both, an overlap condition referred to as *critical illness polyneuromyopathy* (CIPNM).

PATHOBIOLOGY

For CIM, corticosteroids, nondepolarizing neuromuscular blocking agents, or both are considered the prime inciting factors, but it has appeared in some individuals who received neither agent. Patients undergoing treatment for status asthmaticus, organ transplantation, and severe trauma seem to be particularly vulnerable. Female gender was found to be independently linked to the development of CIPNM. In contrast, for CIP, sepsis, systemic inflammatory response syndrome, and multiorgan failure are risk factors. Other factors that may contribute to CIM and CIP include severity of the illness, duration of ICU stay, duration of organ dysfunction, renal failure, hyperosmolarity, hyperglycemia, and vasopressor and catecholamine supportive treatment.

Pathophysiologic mechanisms responsible for these conditions are not fully understood. Loss of myosin is a hallmark of the more traditional form of CIM and can be appreciated as selective rarefaction of the thick filaments on electron microscopy. In patients with CIM, direct muscle stimulation has shown a loss of muscle fiber excitability, which has been attributed to voltage-gated sodium channel fast inactivation, based on animal models of steroid-treated denervated muscle as well as biopsied muscle. Enhanced expression of ubiquitin, lysosomal enzymes, and calcium-activated proteases (calpains) has been observed in muscle and could play a pathogenic role. These catabolic pathways may be activated in muscle by induction of transforming growth factor-β/mitogen-activated protein kinase pathways. Immune activation by cytokines may also contribute to the myopathy.

Although direct evidence is lacking, CIP has been attributed to microcirculation defects including increased vessel permeability and vasodilation leading to the axonal degeneration. Peripheral nerve biopsies from CIP patients have revealed expression of E-selectin in the vascular endothelium of epineural and endoneurial vessels. Because E-selectin is not normally expressed in vascular endothelium, its presence may increase nerve microvasculature permeability, which would allow circulating neurotoxins to enter the endoneurium and promote endoneurial edema.

TABLE 95.1 Major Characteristics of Critical Illness Myopathy and Critical Illness Polyneuropathy

	Critical Illness Myopathy	Critical Illness Polyneuropathy
Clinical features	Weakness, typically diffuse including respiratory muscles. Muscle atrophy is common.	Distal limb weakness and sensory loss with diminished or absent tendon reflexes. Respiratory muscle weakness is common.
Risk factors	Treatment with corticosteroid, nondepolarizing neuromuscular blocking agent, or both	Sepsis, systemic inflammatory response syndrome, multiorgan failure
Nerve conduction study and electromyography abnormalities	Myogenic abnormalities	Neurogenic abnormalities with signs of acute denervation
Muscle biopsy findings	Myofiber atrophy predominantly affecting type 2 fibers. Loss of thick (myosin) filaments is characteristic but is not always seen.	Signs of acute denervation
Treatment	Reduce exposure to corticosteroids and nondepolarizing neuromuscular blocking agents.	Intensive insulin treatment to maintain normal blood glucose levels

DIAGNOSIS

Clinical Manifestations

In CIM, severe quadriplegia and muscle atrophy commence 4 to more than 100 days after initiation of intensive care therapy. The weakness may be primarily distal or proximal but is usually diffuse; many patients lose tendon reflexes. Ophthalmoparesis and facial muscle weakness are occasionally present. Persistent respiratory muscle weakness complicates weaning patients from mechanical ventilation. Improvement is generally evident in 1 to several months in most individuals who survive their critical illness, but protracted recovery or persistent deficits are common.

CIP presents as acute distal limb weakness and sensory loss with diminished or absent tendon reflexes. Involvement of the phrenic and intercostal nerves causes respiratory muscle weakness that often requires prolonged mechanical ventilation therapy (Table 95.1). Autonomic failure and pupillary changes are not expected manifestations of CIP or CIM.

Diagnosis of CIM and CIP is typically suspected when patients have unexplained severe limb weakness, inability to wean patients off mechanical ventilation, or both. Marked muscle atrophy is common in CIM, whereas areflexia and stocking-glove sensory loss (in alert patients) are characteristics of CIP. CIM and CIP must be distinguished from the persistent weakness that may follow administration of nondepolarizing blocking agents to a person with impaired hepatic metabolism, reduced renal excretion, or both.

Laboratory Testing and Electrophysiology

In patients with CIM, serum creatine kinase levels are usually normal but can be elevated in the acute necrotizing subtype of CIM. Nerve conduction studies demonstrate absent or low-amplitude compound motor action potentials with decreased duration and polyphasia. Sensory nerve action potentials are usually normal in CIM, but they can be reduced or absent due to coexisting neuropathy or technical constraints in the ICU environment such as interference from surrounding devices, hypothermia, or limb edema. Electromyography variably shows signs of denervation from muscle necrosis and myogenic or normal motor unit action potentials; however, motor unit and recruitment analysis are frequently suboptimal owing to severe weakness, encephalopathy, sedation, or other confounding factors. Direct muscle stimulation has shown a loss of muscle fiber excitability. Increased insertional activity in the form of fibrillation potentials, positive sharp waves, or both is seen in most cases of CIM.

In CIP, nerve conduction studies typically show signs of axonopathy with decreased or absent sensory nerve action potentials and compound motor action potentials with mildly reduced conduction velocities; these changes may appear as early as 72 hours after ICU admission and can precede clinical manifestations. Electrophysiologic studies of the peroneal nerve have been proposed as a rapid and sensitive diagnostic test for CIP. Electromyography shows fibrillations and positive sharp waves due to acute denervation, which can be difficult to distinguish acute muscle necrosis.

Muscle Biopsy

Muscle biopsies in CIM demonstrate myopathic changes. Three distinct histologic features have been described in skeletal muscle biopsies; the abnormalities may be present in isolation or in variable combinations. Muscle fiber atrophy, often more prominent in type 2 fibers, is routinely seen. In patients with markedly elevated creatine kinase levels, necrosis of muscle fibers has been observed. The most striking feature revealed by electron microscopy is loss of thick (myosin) filaments, corroborated by antimyosin-antibody stains and reduced myosin messenger RNA levels but is not seen in many cases.

Muscle biopsies in CIP can show signs of acute denervation and reinnervation. Nerve biopsies are generally not useful in CIP, which typically manifests nonspecific signs of axonal neuropathy affecting both motor and sensory nerves; however, if other forms of peripheral neuropathy (eg, vasculitis or chronic inflammatory demyelinating polyneuropathy) are suspected, then nerve biopsies may be indicated.

MANAGEMENT

Treatment of patients with CIM and CIP is primarily directed at the underlying acute medical condition(s). Supportive care, particularly mechanical ventilation, is important. Because corticosteroids and neuromuscular blocking agents appear to trigger CIM, reducing exposure to these agents is generally recommended. Venous thromboembolism prophylaxis and pressure ulcer prevention are central to the care of patients with CIM and CIP.

Two randomized trials of ICU patients have demonstrated that intensive insulin treatment aimed at maintaining normal glucose levels reduces the incidence of CIP and CIM by nearly half (relative risk, 0.65; 95% confidence interval, 0.55-0.77) as well as duration of mechanical ventilation and 180-day mortality compared to conventional insulin treatment LEVEL 1.[1,2] Immune modulation is currently being investigated in the treatment of ICU-acquired weakness. So far, intravenous immunoglobulin has not shown benefit in a randomized controlled trial. Physical therapy to passively stretch muscles may reduce muscle atrophy and may increase functional independence. In one randomized controlled trial, electrical muscle stimulation was shown to improve muscle strength and reduce the duration of weaning from mechanical ventilation in patients with CIPNM

OUTCOME

Both CIM and CIP cause prolonged and often severe disability. The weakness can persist for months to years or even indefinitely. About 28% of patients with CIP, CIM, or both may not recover ability to ambulate independently or wean completely off ventilation. CIP is more likely to cause permanent disability than CIM. The majority of patients with CIM recover in 3 to 6 months. Of those patients with CIP who completely recover, most will do so within 6 to 12 months, with a quarter recovering between 12 and 24 months.

Endocrine and Toxic Myopathies 96

Christina M. Ulane

KEY POINTS

1. Thyroid disorders and corticosteroid abnormalities (most often from exogenous sources) are the most common endocrinopathies associated with myopathy.
2. Weakness patterns due to corticosteroids used in autoimmune neuromuscular disorders, such as myasthenia gravis, can overlap with the underlying condition.
3. Workup involves identifying underlying conditions as well as creatine kinase and electromyography.
4. Toxic myopathies are an important consideration, either due to environmental exposures such as alcohol or as a side effect of medications, particularly statins and certain chemotherapeutics.

INTRODUCTION

Muscle comprises a large proportion of all tissues in the body, and the energy required for its function renders it susceptible to metabolic abnormalities from endocrine dysfunction and toxic effects of medications and environmental exposures. Muscle tissue is affected by the metabolic and trophic effects of various components of the endocrine system and by direct and indirect effects of toxins. With the rapid development of new treatments for a wide variety of diseases, particularly the immune checkpoint inhibitors used in cancer, new causes for toxic myopathies arise. This chapter highlights features of the most common endocrinopathies and toxins affecting muscle, concisely reviews the many others, and emphasizes the fundamental principles in diagnosis and treatment of these disorders.

ENDOCRINE MYOPATHIES

Epidemiology

Myopathy in endocrine disorders is rather common, but the earlier diagnosis and treatment of endocrinopathies has reduced the severity of myopathic symptoms. Thyroid disorders and corticosteroid abnormalities (most often from exogenous sources) are the most common endocrinopathies encountered and thus discussed in most detail. Exogenous corticosteroid administration at doses of 30 mg or more per day of prednisone confers the highest risk.

Neuromuscular symptoms in hypothyroidism are reported to be found in up to 80% of patients. Historical studies suggest that up to 75% of patients with hyperthyroidism will experience myopathy, but current data regarding incidence of true myopathy in endocrinopathies is not available, likely a result of earlier diagnosis and treatment. Myopathy is also found in association with acromegaly, hypopituitarism, hyperparathyroidism, and hypoparathyroidism.

Pathobiology

The exact basis of myopathy in endocrinopathy is unknown and may be multifactorial. Often, weakness and fatigue are out of proportion to muscle wasting, suggesting energy failure as a mechanism. Thyroxine has catabolic effects on muscle, may reduce efficiency of muscle contraction, alter membrane excitability and lead to reduced potassium in muscle and serum, leading to weakness in hyperthyroidism. Hypothyroidism reduces glycogenolysis (animal studies indicate this occurs via reduced expression of β-adrenergic receptors on muscle cells), which may be responsible for cramps and fatigue. Hypothyroidism can also reduce mitochondrial oxidation, and studies in rats demonstrate changes in myosin from fast-twitch to slow-twitch muscle types. Thyroid-associated ophthalmopathy leads to edema in the extraocular muscles from both glycoprotein accumulation and inflammation. Corticosteroids cause muscle catabolism and stimulate protein degradation.

Diagnosis

Clinical Features

Myopathy from endocrine disorders causes nonspecific symptoms of myopathy. Proximal limb weakness, fatigue, and cramps are common. In some cases, myalgias are present. In corticosteroid myopathy, symptoms may occur as early as after a few weeks of treatment. See **Table 96.1** for clinical features of thyroid-associated myopathies and **Table 96.2** for other endocrine-associated myopathies, including that due to exogenous corticosteroid administration.

Diagnostic Testing

Other features related to specific endocrine disorders are usually apparent and suggest the diagnosis (see **Tables 96.1** and **96.2**). However, if corticosteroids are being used for the treatment of a disease that also causes weakness (such as inflammatory myositis or myasthenia gravis), it can be challenging to determine whether progression of the underlying disorder or the corticosteroid treatment is the cause of weakness. Laboratory testing for serum levels of thyroid function, adrenocorticotrophic hormone, cortisol, metabolic panel, parathormone, and growth hormone can be diagnostic. Serum creatine kinase (CK) and electrolyte levels are helpful in many cases.

Electromyography (EMG) testing may be normal but will often show myopathic abnormalities and, occasionally, signs of irritative myopathy. Muscle biopsy may be required to distinguish other underlying causes, but findings in endocrine

TABLE 96.1 Myopathies Associated With Thyroid Disorders

Disorder	Clinical	Diagnostics	Treatment
Hypothyroidism	• Muscle stiffness, pain, and cramps, especially with cold and exercise • Delayed relaxation (pseudomyotonia) • May have associated sensorimotor polyneuropathy • Can result in rhabdomyolysis • Associated with fatigue, weight gain, cold intolerance, constipation, dry skin, bradycardia	• TSH is elevated; free T_3 and T_4 are low. • CK normal or elevated up to 10× normal • EMG: normal or myopathic, +/− fibrillations, positive sharp waves • Biopsy: normal or nonspecific changes such as type 2 fiber atrophy • Rarely due to central hypothyroidism: normal TSH but low free T_4	• T_4 supplementation (Start 25-50 μg daily, increase to 1.6 μg/kg/d, and monitor TSH.)
Hyperthyroidism	• May be acute or insidious in onset • Proximal weakness, wasting (shoulder girdle, scapular winging) • May involve respiratory, bulbar, or distal muscles • Ophthalmopathy with Graves disease • Associated with anxiety, tremor, palpitations, weight loss, heat intolerance, tachycardia	• CK is normal (except in thyroid storm). • EMG: normal or myopathic in proximal muscles • Biopsy: nonspecific, type 1 and 2 fiber atrophy	• Correction of T_4 levels to normal (antithyroid medications, radioactive iodine, thyroidectomy) • Weakness may take months to resolve. • Propranolol (start 10 mg 3 times a day-4 times a day; may increase to 40 mg 4 times a day) may hasten recovery.
Thyrotoxic periodic paralysis	• Severe weakness lasting hours to days, precipitated by cold, exercise, or high-carbohydrate intake, insulin or β-agonists (causing hypokalemia) • Associated with hyperthyroid state • More common in men from Japan and China	• Potassium levels low during attacks • +/− Low magnesium or phosphorus • Associated HLA haplotypes	• Correction of thyroid abnormality • Potassium supplementation as needed • Propranolol (start 10 mg 3 times a day-4 times a day; may increase to 40 mg 4 times a day) may prevent attacks.
Thyroid ophthalmopathy	• Exophthalmos, pain, diplopia • May have compressive optic neuropathy • Mostly occurs with hyperthyroidism (sometimes with hypothyroidism, euthyroidism)	• Edema of extraocular muscles on MRI	• Correction of thyroid abnormality • Guanethidine eye drops (β-adrenergic) • Local steroid injection • Systemic steroids (prednisone 30-100 mg orally daily for at least 4 wk followed by taper or methylprednisolone 500 mg IV for one dose followed by 250 mg IV weekly) • Selenium 100 mg twice a day for 6 mo

Abbreviations: CK, creatine kinase; EMG, electromyography; HLA, human leukocyte antigen; IV, intravenous; MRI, magnetic resonance imaging; T_3, triiodothyronine; T_4, thyroxine; TSH, thyroid-stimulating hormone.

myopathies are usually nonspecific. Please see Tables 96.1 and 96.2 for laboratory, EMG, and muscle biopsy findings in various endocrine myopathies.

Management

Treatment is directed at correcting the underlying endocrine abnormality, through hormone replacement therapy or by reducing circulating hormone levels. In the case of hyperthyroid myopathy, propranolol may improve time to recovery through β-adrenergic blockade. If exogenous corticosteroids are the cause for myopathy, treatment of the disease for which the steroids are indicated must be balanced with reducing the contribution of steroids to the myopathy. Several strategies can be helpful, including alternate-day dosing and the use of steroid-sparing agents when possible (see Tables 96.1 and 96.2).

Outcome

Most persons with endocrinopathy causing myopathy will recover completely with correction of the underlying abnormality. Rarely, in Cushing disease, recovery may be incomplete.

TOXIC MYOPATHIES

Epidemiology

Toxic myopathies arise from environmental exposures and increasingly often from medications (Table 96.3). The large number of people prescribed statin medications makes this potentially myotoxic agent a commonly encountered clinical problem. Up to 20% of people taking statins will experience myalgias or cramps, and asymptomatic CK elevation occurs in up to 5% of patients treated with statins. Symptom onset is most commonly within the first 6 months of statin use but may occur at any time. It is important to note that 30% to 50% of patients taking statins who experience myalgias have another possible cause for the myalgias. Most statin myotoxicity is mild and self-limited; however, severe necrotizing myopathy can occur in rare cases. Only about 0.08% of patients taking lovastatin, simvastatin, or pravastatin were found to develop severe myopathy with pain and proximal weakness. Certain statins pose greater risk (atorvastatin, simvastatin, and pravastatin), whereas others are associated with lower risk (fluvastatin, rosuvastatin) for toxicity. In 2001, cerivastatin was withdrawn from

TABLE 96.2 Myopathies Associated With Other Endocrinopathies

Disorder	Clinical	Diagnostics	Treatment
Cushing disease/ exogenous corticosteroid administration	• Painless proximal weakness (legs affected more than arms) • +/− Muscle wasting • Fluorinated corticosteroids more likely to cause myopathy (triamcinolone, betamethasone, dexamethasone)	• CK is normal. • EMG: may be normal or show myopathic features • Biopsy: type 2 fiber atrophy; increased glycogen	• Treat underlying Cushing etiology, but recovery may be slow or incomplete. • Reduce exogenous steroid dose to minimum possible. • Alternate-day steroid dosing • Use of nonfluorinated corticosteroids • Use of steroid-sparing agents
Adrenal insufficiency	• General weakness • Fatigue, cramps	• CK is normal. • EMG: normal • Biopsy: nonspecific	• Glucocorticoid replacement. Hydrocortisone 5 mg/m^2 total daily; given twice a day with two-thirds of dose in AM and one-third in PM
Acromegaly	• Slowly progressive proximal weakness and pain • Decreased exercise tolerance • Minimal muscle wasting • Associated carpal tunnel syndrome, radiculopathies	• CK is normal or mildly elevated. • EMG: +/− myopathy • Biopsy: hypertrophy or atrophy of type 1 and 2 fibers, excess lipofuscin, glycogen	Correction of excess GH: • Bromocriptine: Start 1.25-1.5 mg daily; increase to 20-30 mg daily. • Pituitary adenoma resection • Irradiation
Hyperparathyroidism	• Generalized weakness, stiffness • Proximal weakness, wasting (especially legs) • Tongue fasciculations • +/− Hyperreflexia • Encephalopathy, hallucinations • Chronic renal failure (secondary hyperparathyroidism)	• CK is normal. • Hypercalcemia, hypophosphatemia, hypomagnesemia • EMG: +/− myopathic • Biopsy: nonspecific	• Parathyroidectomy
Osteomalacia	• Proximal weakness and myalgias	• CK is normal or mildly elevated. • EMG: myopathic • Biopsy: nonspecific	• Vitamin D supplementation (50,000 units vitamin D_2 or D_3 weekly for 6 wk and then 800 units D_3 daily) • Supplementation as needed: calcium 1,000 mg daily and phosphorus 30-80 mmol total daily given 3 times a day or 4 times a day.

Abbreviations: CK, creatine kinase; EMG, electromyography; GH, growth hormone.

the market in connection with cases of fatal rhabdomyolysis. Rhabdomyolysis due to statins is rare, with an incidence of 2 to 3 per 100,000 patient-years.

Myotoxicity from statin use is increased in patients with obesity, preexisting hepatic or renal disease, hypothyroidism, and advanced age. There is also a dose-dependent myotoxic effect: For patients on simvastatin, 1.6% show symptoms on 80 mg/d versus 0.1% on 20 mg/d. Risk of statin myotoxicity is increased with concomitant use of medications that inhibit cytochrome P450 3A4 (*CYP3A4*) pathway, which affects statin metabolism. In particular, statin use with gemfibrozil or cyclosporine significantly increases the risk of statin toxicity. Use of other medications metabolized by the *CYP3A4* pathway (such as calcium channel blockers, antibiotics, antidepressants, and antiretrovirals) can increase serum levels of statins and thus the risk of myotoxicity.

Genome-wide association studies identified a single nucleotide polymorphism in the *SLCO1B1* gene that predisposes to statin-induced myopathy. This gene encodes a protein involved in the hepatic uptake of statins, and persons homozygous for the polymorphism (2% of the general population) have increased serum levels of statins and 15% develop self-limited statin myopathy (not the immune-mediated necrotizing myopathy).

Immune checkpoint inhibitors have emerged recently as an etiology for myotoxicity, with unclear incidence but overall immune-related neurologic events are estimated to occur in up to 2.9% of patients treated with anti–program cell death protein 1 (PD-1) inhibitors.

Pathobiology

Toxins cause myopathy either by directly affecting the muscle or indirectly through electrolyte imbalance or triggering immune reactions. Various types of pathophysiology account for toxic myopathies (see Table 96.3). Toxins may induce necrotizing myopathy, as with alcohol and statins. Autophagic lysosomal pathology is seen with amphiphilic agents such as chloroquine and amiodarone. Colchicine and vincristine-induced myopathy through antimicrotubular effects. Many agents can cause an inflammatory myopathy. Antiretroviral agents lead to mitochondrial myopathy, and diuretics and laxatives among others cause hypokalemic myopathy. Self-limited statin myotoxicity likely is due to muscle membrane destabilization secondary to reduced levels of lipid precursors, vitamin D, dysfunction of mitochondrial electron transport, and coenzyme Q10 production (Fig. 96.1). Statins may cause a severe toxic necrotizing myopathy, or an immune-mediated necrotizing myopathy associated with anti-HMGCR antibodies and upregulation of complement membrane attack complex (MAC) and major histocompatibility complex class 1 (*MHC-1*) receptors on biopsied nonnecrotic muscle fibers. The immune-mediated necrotizing myopathy caused by statins is discussed in detail in Chapter 94.

Immune checkpoint inhibitors act by targeting the mechanisms used by cancer to evade the immune response and result in upregulation of the immune system. This in turn causes diverse off-target immune-related adverse events affecting many different organ systems including neurologic effects such as neuropathy, encephalopathy, meningitis, and myositis/myasthenia gravis.

TABLE 96.3 Toxic Myopathies

Pathophysiology	Medications/Toxins and Associated Features
Necrotizing[a]	Statins[c] • Severe toxic necrotizing myopathy or immune-mediated necrotizing myopathy: associated with anti-HMGCR antibodies, upregulation of *MHC-1* and MAC on nonnecrotic fibers on muscle biopsy Other cholesterol-lowering agents (fibrates, red yeast rice)[c] Immunophilins • Cyclosporine[c] • Tacrolimus Ethanol Labetalol, propofol (rare) Snake venom
Amphiphilic (autophagic lysosomal)	Chloroquine/hydroxychloroquine[c] • Often with polyneuropathy • May have associated cardiomyopathy • Correlates with duration of use and dose • Vacuoles on muscle biopsy Amiodarone • Often with polyneuropathy • Also causes hypothyroidism, tremor, ataxia • Vacuoles on muscle biopsy
Antimicrotubular	Colchicine[c] • Often with polyneuropathy • Vacuoles on muscle biopsy Vincristine
Hypokalemic	Diuretics Laxatives Amphotericin Toluene Licorice Corticosteroids • Normal EMG • Type 2 fiber atrophy on muscle biopsy Ethanol • Normal EMG • Type 2 fiber atrophy on muscle biopsy
Mitochondrial[b]	Zidovudine Other antiretrovirals
Inflammatory	Immune checkpoint inhibitors (often myositis with myasthenia gravis) L-tryptophan D-penicillamine Phenytoin Lamotrigine Interferon-α Hydroxyurea Imatinib (20%-50% will have myalgias) Tumor necrosis factor inhibitors Cimetidine (rare; with interstitial nephritis)
Unknown/other	Omeprazole Levetiracetam Finasteride Isotretinoin Emetine Febuxostat

Abbreviations: EMG, electromyography; HMGCR, 3-hydroxy-3-methylglutaryl coenzyme A reductase.
[a]May be acute in onset and painful.
[b]Ragged red/blue fibers on muscle biopsy.
[c]May exhibit myotonic discharges on EMG.

Diagnosis

Clinical Features

Symptoms of toxic myopathies are nonspecific, and clinical presentation may be diverse. Proximal weakness is common, with or without associated pain. Rarely are the respiratory and bulbar muscles affected. In general, myopathy due to drugs is infrequent, and thus, a high index of suspicion is essential to identify the connection. Depending on the drug, dose, and patient characteristics, the symptoms may vary from mild (cramps and myalgias) to severe (necrotizing myopathy with weakness, rhabdomyolysis). Although most patients will exhibit symptoms shortly after beginning a medication, in others, symptoms may develop more insidiously over time, and thus, causality can be difficult to establish.

Myositis from immune checkpoint inhibitors begins early (often within a month) after therapy initiation and can occur with cytotoxic T-lymphocyte-associated protein 4 (CTLA-4), PD-1, or programmed death-ligand 1 (PD-L1) inhibitors. Proximal weakness and occasionally bulbar and respiratory involvement are seen; there is also overlap with myasthenia gravis (CK levels can help distinguish).

Diagnostic Testing

History and temporal correlation with medication use are crucial in determining whether a toxin is the cause of myopathy. Resolution of symptoms following withdrawal of the potentially offending agent is helpful in diagnosis.

Laboratory studies including CK, metabolic panel, hepatic function testing, thyroid function testing, and vitamin D can not only assist in diagnosis but also aid in identifying readily correctable abnormalities that may worsen myopathy. EMG may show myopathic findings. In rare instance, a muscle biopsy may be necessary, and on occasion, a myotoxic medication may identify an underlying metabolic or hereditary myopathy.

Management

Most often, removal of exposure to the offending agent will reduce or resolve myopathy completely. In the case of statin-associated immune-mediated necrotizing myopathy, ongoing immunosuppressive treatment is needed (see Chapter 94). Results are mixed as to whether supplementation with coenzyme Q10 is beneficial for statin-associated myopathy. Vitamin D supplementation is recommended only for those with laboratory evidence of deficiency, and it is unclear if it is helpful in the absence of deficiency. The high prevalence of dyslipidemia and ensuing statin use suggests a tiered approach to the treatment of statin-associated myopathy (Table 96.4). The American College of Cardiology provides an online tool called the *ACC's Statin Intolerance Tool* to help risk stratify and clarify whether a patient is truly intolerant of a statin or whether treatment modifications can be made. There is also the "Statin-Associated Muscle Symptom Clinical Index," which can help clinicians assess the likelihood that a patient's muscle symptoms are due to statin use.

Outcome

Prognosis for toxic myopathies depends on the etiology and specific syndrome. In general, withdrawal of the offending agent results in resolution or significant improvement of myopathy.

FIGURE 96.1 **A:** Simplified schematic for cholesterol synthesis, the generation of isoprenylated proteins and coenzyme Q10 (CoQ10) and the role of statins (β-hydroxy β-methylglutaryl-coenzyme A [HMG-CoA] reductase inhibitors) in this pathway. **B:** Downstream effects of statins on muscles. Reduced levels of cholesterol, vitamin D, and isoprenylated proteins have pleiotropic effects on skeletal muscle function. Abbreviations: HMGCR, 3-hydroxy-3-methylglutaryl coenzyme A reductase; IMNM, immune-mediated necrotizing myopathy .

TABLE 96.4 Myotoxicity Associated With Statins

Syndrome	Management
Asymptomatic hyperCKemia	• May continue statin • Monitor CK and for clinical symptoms.
Myalgias, cramps	• Discontinue statin; most symptoms will resolve in 2-3 mo. • Retrial at lower dose or switch to lower risk statin • If symptoms persist or progress, consider muscle biopsy for underlying neuromuscular disorder or myositis. • Potential role for vitamin D (mainly in those with deficiency), coenzyme Q10
Toxic necrotizing myopathy	• Discontinue statin (improve within 2-3 mo). • Hospital admission • Intravenous hydration • Supportive measures • Hemodialysis if needed • Risk/benefit analysis regarding need for statin
Immune-mediated necrotizing myopathy (with anti-HMGCR antibodies)	• Discontinue statin (myopathy persists or progresses despite discontinuation). • Long-term immunosuppressive treatment (see Chapter 94)

Abbreviations: CK, creatine kinase; HMGCR, 3-hydroxy-3-methylglutaryl coenzyme A reductase.

97 Periodic Paralysis and Other Channelopathies

Comana M. Cioroiu

KEY POINTS

1. Muscle channelopathies comprise a heterogeneous group of diseases of skeletal muscle that include both syndromes of episodic weakness (periodic paralyses) and muscle fiber hyperexcitability (nondystrophic myotonias) and these entities can overlap.
2. Most of these disorders are inherited in an autosomal dominant manner due to specific channel mutations.
3. Hypokalemic periodic paralysis occurs with episodes lasting greater than 2 hours triggered by rest after exercise, alcohol, and meals rich in carbohydrates. It is associated with mutations in the *CACNA1S* calcium channel gene or *SCN4A* sodium channel gene.
4. Hyperkalemic periodic paralysis occurs with episodes lasting less than 2 hours triggered by potassium-rich foods, exercise, fasting, and exposure to cold. It may coexist with paramyotonia congenita and is associated with mutations in the *SCN4A* sodium channel gene.
5. Andersen-Tawil syndrome is a syndrome characterized by a clinical triad of periodic paralysis, ventricular arrhythmias with a prolonged QT interval, and dysmorphic features.
6. Paramyotonia congenita is characterized by stiffness that worsens with repeat exercise and cold temperatures and is associated with a mutation in the *SCN4A* sodium channel gene.
7. Myotonia congenita (Thomsen disease) is characterized by stiffness that improves with repeat exercise ("warm-up phenomenon") and is associated with a mutation in the *CLCN1* chloride channel gene.
8. Episodes of periodic paralysis may be prevented by treatment with carbonic anhydrase inhibitors acetazolamide and dichlorphenamide.

INTRODUCTION

Muscle channelopathies comprise a heterogeneous group of diseases of skeletal muscle that include both syndromes of episodic weakness (periodic paralyses) and muscle fiber hyperexcitability (nondystrophic myotonias). The clinical phenotype depends on the particular channel mutation involved, and attacks can vary in severity, duration, and constellation of symptomatic triggers (**Table 97.1**). Most of these disorders are inherited in an autosomal dominant fashion, although sporadic mutations do exist. Changes in neuronal membrane depolarization secondary to various ion channel mutations can either lead to sustained depolarization and resultant overt muscle weakness or to a more mild constant depolarization (or reduced repolarization) leading to myotonia and stiffness. On occasion, there is overlap between the two, and some patients may have episodes of both myotonia and paralysis. There are three main types of periodic paralysis: hypokalemic periodic paralysis (hypoKPP), hyperkalemic periodic paralysis (hyperKPP), and Andersen-Tawil syndrome (periodic paralysis with cardiac arrhythmia and dysmorphic features). The nondystrophic myotonic disorders are primarily composed of myotonia congenita (MC), paramyotonia congenita (PC), as well as a subgroup of potassium-aggravated myotonic disorders. Electrodiagnostic testing is important in helping to identify particular patterns and make a correct diagnosis. Needle electromyogram (EMG) is needed to detect myotonic discharges or other abnormal spontaneous activity. In addition to routine nerve conduction studies, short and long exercise tests are uniquely used to help characterize specific patterns. In short exercise testing, the patient is asked to exercise a muscle (typically the abductor digiti minimi), and a compound muscle action potential (CMAP) is recorded every 10 seconds thereafter and compared to a baseline. In the long exercise test, the patient is asked to exercise the muscle for an extended amount of time (usually 5 min), and CMAPs are recorded every 2 minutes thereafter for about 1 hour and compared to baseline. Changes in CMAP amplitude in both short and long exercise testing can be used to differentiate between the various channelopathies. For instance, CMAP amplitudes typically increase in the periodic paralyses and decrease in the myotonias. Different electrodiagnostic patterns diagnostic of each particular disease were described in 2004 by Emmanuel Fournier and are still used today and are known as *Fournier patterns*. Targeted confirmatory genetic testing is often done thereafter to confirm the diagnosis. Although patients with these diseases have a normal life expectancy, they may struggle with persistent pain or progressive weakness causing significant functional impairment.

HYPOKALEMIC PERIODIC PARALYSIS

Epidemiology and Pathobiology

Hypokalemic periodic paralysis is the most common of the periodic paralyses; yet, it is still rare, affecting only about 1.7 per 1,000,000 people in England. Clinical onset is usually within the first 2 years of life (although it may be delayed into the sixth decade) and is more prevalent in men than women in a ratio of about 2:1. Most of these patients have mutations in either the *CACNA1S* gene (CaV1.1, chromosome 1q31-32) encoding an L-type calcium channel or, less commonly, the *SCN4A* sodium channel gene (NaV1.4, chromosome 17q23). In the presence of these mutations and low extracellular potassium, muscle fibers become

TABLE 97.1 Clinical Features of Hereditary Periodic Paralysis and Nondystrophic Myotonias[a]

	Hypokalemic Periodic Paralysis	Hyperkalemic Periodic Paralysis	Andersen-Tawil Syndrome	Paramyotonia Congenita	Myotonia Congenita
Gene	*CACNA1S* or *SCN4A*	*SCN4A*	*KCNJ2*	*SCN4A*	*CLCN-1* (AD) or *SCN4A* (AR)
Age of onset	Usually second or latter part of first decade	First decade	First or second decade	First decade	First decade
Sex	Male preponderance	Equal	Equal	Equal	Male preponderance
Frequency of paralytic episodes	Daily to yearly	Hourly to daily	Daily to yearly	May not be present; otherwise, weekly to monthly	Usually not present, variable frequency in AR form
Degrees of paralysis	Tends to be severe	Tends to be mild but can be severe	Variable	Tends to be mild but can be severe	Lasting seconds to minutes in AR form, usually not present in AD form
Effect of cold	May induce an attack	May induce an attack	May induce an attack	Tends to induce an attack	No effect
Oral potassium	Relieves or prevents an attack	Precipitates an attack	May relieve or prevent an attack	May precipitate an attack	No effect
Myotonia	Absent	May be present	Absent	Present	Present
Precipitants	Carbohydrate-rich food, cold	Fasting, stress, rest after exercise, K-rich foods	Carbohydrate-rich food, rest after exercise	Fasting, stress, cold, rest after exercise	Exercise
Exercise testing	Increase in CMAP with gradual decline with long exercise testing; short exercise testing normal (Fournier V)	Increase in amplitudes with gradual decrease in both short and long exercise testing (Fournier IV)	Unknown	Prominent drop in amplitudes with cooling in both long and short exercise testing; PEMPs present (Fournier I)	AD: drop in amplitude on short exercise testing, less drop with repeated testing AR: drop in amplitude with slow recovery (Fournier II)

Abbreviations: AD, autosomal dominant; AR, autosomal recessive; CMAP, compound muscle action potential; K, potassium; PEMP, postexercise myotonic potential.

depolarized and electrically inexcitable, leading to weakness. Just how these mutations cause persistent depolarization is unknown; however, one mouse model of such a calcium channel mutation proposed a possible explanation via a "gating pore current," described as an anomalous inward current at the resting potential triggered by low extracellular potassium content, leading to depolarization and sodium channel inactivation. At the structural level, mutations in the calcium channel lead to a vacuolar myopathy, whereas sodium channel mutations are associated with the development of transverse tubular aggregates and less vacuolization.

Clinical Manifestations and Diagnosis

Patients with hypoKPP typically note transient weakness after a period of rest after exercise with associated hypokalemia. These episodes are often more prominent during sleep or on rising in the morning and are worse after alcohol or a meal rich in sodium or carbohydrates. The extent of paralysis can be variable and asymmetric and can vary from slight leg weakness to complete flaccid quadriplegia. Bulbar and respiratory muscles are typically spared, but urinary or fecal retention may be seen. Attacks commonly occur between age 5 and 35 years and decrease with age. The duration of attacks can be variable and last anywhere from a few hours to several days. The interval between attacks may be as long as 1 year, although in some patients, attacks can occur daily. Patients have normal strength in between attacks, but some eventually develop fixed proximal weakness. Attacks may be associated with pain either preceding or following weakness. In a mild attack, tendon reflexes are diminished in proportion to the degree of weakness and are completely absent in a severe attack. Sensation remains normal. These patients are at increased risk for weakness in the setting of anesthesia.

Diagnosis can be made on the basis of the presence of similar attacks of transient weakness in family members. Confirmatory tests include the finding of low potassium content (3.0 mEq/L or less) and high sodium content in the serum during an attack and the ability to induce an attack with an intravenous infusion of glucose and regular insulin. Serum creatine kinase (CK) levels are typically normal or mildly elevated. Short exercise electrodiagnostic testing is usually normal, but an increase in CMAP amplitude with a delayed decline can be seen with long exercise testing (Fournier pattern V). Needle EMG does not show myotonic discharges. Prior to making a diagnosis of hypoKPP, it is of crucial importance to exclude other conditions that may also lead to periodic paresis and hypokalemia including hyperaldosteronism, diuretic use, gastrointestinal loss, and thyrotoxicosis (Table 97.2). The latter in particular must be considered (particularly in those of Asian ancestry). Also, attacks of hypoKPP have been described in patients with hyperthyroidism linked to the potassium channel β subunit gene *KCNE3*, which responds completely with treatment of the thyroid disorder.

Management and Outcome

Acute attacks may be treated safely with oral potassium (20-100 mEq), and rarely, intravenous potassium can be used, although it comes with the risk of subsequent hyperkalemia and cardiac arrhythmias. Prophylaxis of recurrent attacks is usually accomplished with the carbonic anhydrase inhibitor acetazolamide (Diamox) in doses of 250 to 1,000 mg daily. About 50% of patients respond to acetazolamide, and there is a greater benefit in patients with the *CACNA1S* calcium mutation than in those with the *SCN4A* sodium channel mutation. In fact, on occasion,

TABLE 97.2 Potassium and Paralysis: Noninherited Forms

Hypokalemic
• Excessive urinary loss
• Hyperaldosteronism (Conn syndrome)
• Drugs: glycyrrhizae (licorice), thiazide diuretics, furosemide, chlorthalidone, ethacrynic acid, amphotericin B, duogastrone, barium, corticosteroids
• Pyelonephritis, renal tubular acidosis
• Recovery from diabetic acidosis
• Ureterocolostomy
• Excessive gastrointestinal loss (diarrhea, vomiting, fistula)
• Malabsorption syndrome
• Laxative abuse
• Pancreatic tumor, villous adenoma
• Thyrotoxicosis
Hyperkalemic
• Uremia
• Hypoaldosteronism
• Addison disease
• Potassium-sparing diuretics (ie, spironolactone)
• Excessive intake/supplementation of potassium
• Iatrogenic
• Geophagia

it may worsen attacks in patients with sodium channel mutations. The mechanism whereby it helps attacks of weakness is uncertain but may be related to induction of a mild metabolic acidosis, improved chloride conductance, or activation of the KCa^{2+} channel. There are no randomized controlled studies to support the use of acetazolamide and data to support its use is based on anecdotal evidence and few nonrandomized single blind trials. However, dichlorphenamide, another carbonic anhydrase inhibitor, has been shown to be efficacious in reducing attacks in both hyper- and hypoKPP in randomized placebo-controlled trials LEVEL 2[1] and was recently approved by the U.S. Food and Drug Administration in their treatment at doses of 50 to 200 mg/d. In patients treated with dichlorphenamide, these studies demonstrated not only a significant reduction in both attack frequency and severity but also in quality of life in patients with hypoPP. Other agents that may be beneficial include triamterene (50-100 mg/d) or spironolactone (25-100 mg/d), which promote retention of potassium. More recently, bumetanide (an Na-K-2Cl inhibitor) has been effective in preventing recurrent attacks of weakness and restoring force in a mouse model of hypoKPP with either a NaV1.4 sodium channel or CaV1.1 calcium channel mutation. Patients should be counseled about triggering factors and encouraged to avoid alcohol, strenuous exercise, and meals rich in carbohydrates as well as ensuring adequate hydration. In those cases of hypoKPP secondary to a general medical condition (ie, thyroid disease), the underlying disorder must be treated.

With time, patients with hypoKPP experience less attacks as they age and attacks may cease altogether after age 40 or 50 years. The disease does not shorten overall survival, and death due to respiratory involvement is rare. A progressive and persistent proximal myopathy may develop with time and cause functional impairment and disability. Finally, it should be mentioned that susceptibility to malignant hyperthermia has been linked to the *CACNA1S* gene (although it is usually caused by a mutation in the RYR1 gene encoding a ryanodine receptor), and cases of malignant hyperthermia have been described in patients with hypoKPP. However, to date, no conclusive evidence of a clear genetic link has been found.

HYPERKALEMIC PERIODIC PARALYSIS

Epidemiology and Pathobiology

hyperKPP was first described by Frank Tyler at the University of Utah in 1951, when he recognized a form of periodic paralysis not accompanied by a decrease in serum potassium. The disease is caused by an autosomal dominant genetic mutation with complete penetrance, affecting the *SCN4A* sodium channel gene. It is thought to cause defective inactivation of the sodium channel, thereby resulting in a complete loss of membrane excitability and weakness. Mutations involving the *SCN4A* gene cause three clinical variations of hyperKPP—episodic weakness without myotonia, episodic weakness with myotonia, and episodic weakness associated with PC triggered by cold (to be discussed in a subsequent section of this chapter). Overall prevalence is estimated to be about 1.3 per 1,000,000 people with onset before the age of 10 years. The pathophysiology of hyperKPP was first studied by Rüdel et al in the 1980s and led to the suspicion that a defective sodium channel protein might be responsible. First, using microelectrode studies of intercostal muscle, they confirmed that muscle isolated from patients with hyperKPP was partially depolarized at rest. The abnormal depolarization was blocked by tetrodotoxin, which specifically affects the α subunit of the sodium channel. Patch clamp experiments showed faulty inactivation, leading to the conclusion that excessive sodium influx causes repetitive firing of action potentials (myotonia) and eventual inactivation of the membrane (weakness). Cloning and analysis of the gene encoding the voltage-gated sodium channel identified more than 20 missense mutations in the *SCN4A* gene. Some mutations exhibit both interfamilial and intrafamilial phenotypic variability. Muscle biopsy may reveal intracytoplasmic vacuoles.

Clinical Manifestations and Diagnosis

As opposed to hypoKPP, attacks in hyperKPP tend to occur more frequently in the daytime and are shorter (less than 2 h on average) and less severe. Involvement of bulbar or respiratory muscles is rare. The frequency of attacks varies but they tend to occur more often than those in hypoKPP. Attacks may be precipitated by potassium-rich food, rest after exercise, fasting, stress, and cold temperature. Strength is normal in between attacks, and during attacks, patients are areflexic. Fixed proximal weakness may develop over time in many patients. Minimal clinical myotonia may be observed in about half of patients between attacks, with myotonic lid lag or lingual myotonia.

Serum potassium levels may be normal or elevated during an attack, at times in excess of 5.0 mEq/L. Serum CK can also be normal or mildly elevated. Needle EMG may show fibrillations or myotonic discharges in up to 50% to 75% of patients

(indicative of hyperexcitability and muscle irritation), and later in the clinical course, motor units may become myopathic in appearance. Both short and long exercise testing reveal a rise in CMAP amplitude that decreases over time (Fournier pattern IV). Confirmatory genetic testing for the responsible mutation is often done. As with hypoKPP, noninherited causes of hyperkalemia must be excluded, such as uremia, Addison disease, and excessive potassium supplementation.

Management and Outcome

Attacks may be terminated by administration of calcium gluconate, glucose, and insulin to stabilize cardiac membranes and reduce serum potassium levels. Mild exercise and carbohydrate ingestion at the onset of an attack may also be helpful. Acetazolamide in doses of 250 mg to 1 g orally may reduce the number of attacks or completely abolish them. Dichlorphenamide recently gained U.S. Food and Drug Administration approval for both hypoKPP and hyperKPP as above. Potassium-wasting diuretics such as thiazides can promote urinary excretion of potassium and also be effective clinically. Rarely, β-adrenergic agents can be used as well, although come with a risk of cardiac arrhythmias. In those patients with myotonia, mexiletine may give symptomatic relief but comes with a small risk of cardiovascular effects (including arrhythmias) and an electrocardiogram (ECG) is needed prior to its initiation. Patients are encouraged to avoid fasting, potassium-rich foods, and exposure to cold temperatures. As in hypoKPP, life expectancy is not affected but patients' morbidity may be related to episodic and progressive proximal weakness, and myalgia with muscle stiffness may result from myotonia.

ANDERSEN-TAWIL SYNDROME

Epidemiology and Pathobiology

Also known as *Klein-Lisak-Andersen syndrome*, this rare disease is inherited in an autosomal dominant fashion (with some sporadic cases) and is most frequently due to mutations in the KCNJ2 gene encoding an inward-rectifying potassium channel, and several mutations in this gene exist. However, only about 60% of patients will have a known gene mutation, whereas in the remaining 40%, the cause remains unknown. It accounts for less than 10% of all people with periodic paralysis. The syndrome is characterized by the clinical triad of periodic paralysis, ventricular arrhythmias with a prolonged QT interval, and dysmorphic features, which are usually skeletal abnormalities. Episodes of paralysis can be hyperkalemic, normokalemic, or hypokalemic. Not all patients show the complete triad. The disease typically starts with episodes of periodic paralysis in the first or second decade, and serum levels of potassium vary.

Clinical Manifestations and Diagnosis

Attacks are highly variable in frequency, duration, and severity. There is usually no associated myotonia or weakness in between episodes, but some patients demonstrate mild neck flexor or facial weakness. Developmental abnormalities include hypertelorism, clinodactyly, low-set ears, scoliosis, and syndactyly, and patients are usually short statured and may have a cleft or high-arched palate with a small mandible. Some patients may have cognitive abnormalities. The associated cardiac manifestations of Andersen-Tawil syndrome are inherent and unique to the diagnosis. Over 50% of patients have a prolonged QT syndrome, and an even larger proportion develops arrhythmias such as bidirectional or polymorphic ventricular tachycardia. Ventricular tachyarrhythmias are less frequent and often asymptomatic, although cardiac arrest may occur in up to 10% of patients. Patients must be questioned about any unexplained syncopal events, which may be indicative of an underlying arrhythmia. An ECG is a crucial component of the diagnostic workup because some patients may benefit from pacing or antiarrhythmic agents. Serum potassium concentrations should be assessed at baseline and during attacks of severe weakness. Electrophysiologic testing is often useful, as long as exercise testing shows an immediate increase in CMAP amplitude with a subsequent decline. Genetic testing for the *KCNJ2* gene mutation is confirmatory. As with hyper- and hypoKPP, secondary causes of periodic paralysis must be excluded (including thyroid disease, renal failure, and others).

Management and Outcome

Management of Andersen-Tawil syndrome is aimed at treatment of both the episodic paralysis and the cardiac manifestations, and a multidisciplinary approach is therefore crucial. Treatment of attacks depends on whether they are associated with low or high levels of potassium. Carbonic anhydrase inhibitors may decrease the frequency of clinical attacks, as in other forms of periodic paralysis. Cardiac evaluation includes yearly ECG and Holter monitoring because some patients benefit from a pacemaker or defibrillator. More often, however, pharmacologic agents such as β-blockers and other antiarrhythmics are used to control arrhythmias. Patients must be counseled to avoid medications that may further prolong the QT interval.

NONDYSTROPHIC MYOTONIAS

Epidemiology and Pathobiology

PC (sometimes known as *Eulenburg disease*) is also caused by a mutation in the *SCN4A* sodium channel gene and, given the shared genetic locus, often overlaps with hyperKPP and different phenotypes may exist in the same family. It is typically inherited as an autosomal dominant disorder and symptoms begin early in life. Infants may have difficulty opening their eyes while crying (eyelid-opening myotonia). In PC, poor inactivation of the sodium channel prolongs the neuronal action potential and slows the rate of repolarization, thereby causing a mild state of persistent depolarization leading to clinical myotonia. This phenotype differs from hyperKPP, and there is probably a different kind of functional defect in the *SCN4A* gene in the two syndromes accounting for this variability. Genetic defects causing persistent sodium currents may lead to paralysis via stable and persistent depolarization (hyperKPP), whereas myotonic discharges result from instability of channel activation that is more variable. Histopathologically, muscle biopsy may show myopathic features with intracytoplasmic vacuolization and tubular aggregates.

Also known as *Thomsen disease*, MC is also autosomal dominant and is caused by mutations in the *CLCN1* chloride channel gene. Men are affected more than women. In the autosomal dominant form, changes in chloride channel function lead to a loss of chloride conductance, thereby leading to delayed repolarization

and increased neuronal excitability due to potassium accumulation in T-tubules and resultant membrane depolarization. An autosomal recessive form also exists, also known as *Becker disease*, and involves a mutation in the *SCN4A* sodium channel gene.

Clinical Manifestations and Diagnosis

The first clinical signs of PC are typically seen in the first decade of life. Patients demonstrate "paradoxical" myotonia, which is defined as myotonia or stiffness that worsens with repeated exercise (as opposed to the "warm-up phenomenon" seen in other myotonic syndromes, in which myotonia decreases with exercise). Cold ambient temperatures worsen clinical myotonia and stiffness, and short and long exercise testing in a cooled limb shows a drop in amplitude with a slow recovery (Fournier pattern I). With more trials, a further drop in amplitude can be seen, which is an electrophysiologic equivalent of the paradoxical myotonia seen clinically. Many patients demonstrate postexercise myotonic potentials, which are after discharges of decreasing amplitude seen after exercise. Needle EMG may show signs of muscle irritability in the form of fibrillations and myotonic discharges, which disappear completely with colder temperatures as the muscle weakens. Given the occasional overlap with periodic paralysis, in some patients, cold temperature or potassium intake can induce a paretic attack. Fixed progressive muscle weakness may develop with time.

Symptoms of Thomsen disease begin in the first decade of life with clinical signs of myotonia—for instance, infants may have trouble opening their eyes after crying and may fall when learning to walk. In MC, myotonia demonstrates the classic warm-up phenomenon, whereby the myotonia improves with exercise and repeated muscle contraction. Both percussion and grip myotonia may be observed. Patients are described as being "Herculean" with excessive muscle mass attributed to the nearly constant state of muscle contraction, although they usually do not complain of pain. Episodes of weakness are rare in the autosomal dominant form, but in Becker disease, they may occur at the onset of physical activity, lasting seconds to minutes. Moreover, in these patients, symptoms commence later in life, and they may also develop proximal weakness. Serum CK is typically normal, as is serum potassium. Short exercise testing shows a transient drop in amplitude (more pronounced with cooling in autosomal dominant form) with a smaller drop with repeated trials (corresponding to the warm-up phenomenon seen clinically), consistent with a Fournier II pattern. Long exercise testing shows little if any change and postexercise myotonic potentials may be seen. Genetic testing confirms the diagnosis.

Management and Outcome

Muscle stiffness related to myotonia is often the primary complaint of patients with PC and MC, and strategies aimed at mitigating this pain vary. Mexiletine, a class IB antiarrhythmic medication, has been used for many years for symptomatic relief in both dystrophic and nondystrophic myotonic syndromes. One placebo-controlled trial done by Statland et al in 2012 demonstrated significant improvement in stiffness after mexiletine treatment for 4 weeks in patients with nondystrophic myotonia. Mexiletine is thought to work via enhancement of fast inactivation of sodium channels, although its efficacy is not restricted to only those patients with myotonia related to *SCN4A* (sodium channel) mutations. The medication is generally well tolerated and is typically started at a dose of 150 mg daily and then slowly increased to a dose of 300 mg 3 times per day. Cardiac testing including an ECG is often done prior to initiating the drug trial, particularly in patients with cardiac symptoms or known cardiovascular disease. Some patients may find relief from other medications with different mechanisms of action such as carbamazepine, phenytoin, or diuretics such as acetazolamide or hydrochlorothiazide.

ACKNOWLEDGMENT

The author wishes to acknowledge the contributions of Dr. Lewis P. Rowland (deceased) to prior versions of this chapter.

98 Stiff Person Syndrome and Peripheral Nerve and Muscle Hyperexcitability

Jonathan Perk and Christina M. Ulane

KEY POINTS

1. Excessive muscular excitability may result from inappropriate activation or dysfunction of inhibitory systems.
2. Stiff person syndrome is a central nervous system autoimmune disorder in which the clinical hallmarks are muscle stiffness, episodic spasms, and psychiatric symptoms.
3. Neuromyotonia (Isaacs syndrome) is a peripherally mediated neuronal hyperexcitability syndrome, which may be autoimmune or paraneoplastic.
4. Neuroleptic malignant syndrome and malignant hyperthermia may be fatal and are associated with dopamine blockade and anesthetic agents, respectively.
5. Muscle cramps are common, and most often benign, however, may accompany serious conditions as motor neuron disease.

INTRODUCTION

The terms *muscle stiffness* and *cramps* are used for commonly experienced symptoms that are often transient and benign. Rarely, they may be harbingers of more serious pathology. Persistent limb muscle stiffness arises from involuntary continuous muscle contraction, whereas cramps and spasms are brief contractions. Lesions throughout the motor system have been implicated in generating muscle stiffness or spasm. Excessive muscular activation may result from dysfunction of inhibitory systems in central nervous system (CNS) pathology or inappropriate activation or hyperexcitability in peripheral nervous system pathology. Table 98.1 outlines features of various causes of muscle cramps and stiffness.

STIFF PERSON SYNDROME

In 1956, Moersch and Woltman, senior neurologists at the Mayo Clinic, described patients with a rare clinical syndrome

TABLE 98.1 Disorders Causing Muscle Stiffness and Hyperexcitability

Localization of Abnormality	Disorder	Principal Manifestations	Treatment
Brain, brainstem, and spinal cord	Stiff person syndrome	Rigidity and reflex spasms Anti-GAD65 antibodies	Diazepam, IVIG, treatment of underlying cancer if paraneoplastic
	PERM	Rigidity and reflex spasms, focal neurologic deficits Anti-GlyRα1 antibodies	Similar to stiff person syndrome
	Tetanus	Rigidity and reflex spasms	Diazepam, supportive care
Peripheral nerve	Acquired neuromyotonia (Isaac syndrome)	Stiffness, myokymia, delayed relaxation Anti-VGKC antibodies (anti-CASPR2, anti-LGI1)	Immunotherapy, phenytoin, carbamazepine, mexiletine, treatment of underlying cancer if paraneoplastic
	Schwartz-Jampel syndrome	Stiffness and myotonia	Phenytoin, carbamazepine
	Tetany	Carpopedal spasm	Correction of calcium, magnesium, or acid-base derangement
Muscle	Myotonic disorders	Delayed relaxation, percussion myotonia	Mexiletine, phenytoin, carbamazepine (see Chapter 147)
	Metabolic myopathies	Cramps during intense or ischemic exercise	See Chapter 99 and Section 19.
	Neuroleptic malignant syndrome	Rigidity during dopamine block	Supportive care, bromocriptine, dantrolene
	Malignant hyperthermia	Rigidity during anesthesia	Supportive care, dantrolene
Unknown	Ordinary muscle cramps	Cramps during sleep or ordinary activity	Stretching affected muscle to relieve cramp; medications may be used if severe (see text).

Abbreviations: CASPR2, contactin-associated protein-like 2; GAD65, glutamic acid decarboxylase-65; GlyRα1, glycine receptor subunit alpha 1; IVIG, intravenous immunoglobulin; LGI1, leucine-rich glioma-inactivated protein 1; PERM, progressive encephalomyelitis with rigidity and myoclonus; VGKC, voltage-gated potassium channel.

of progressive fluctuating muscular rigidity and painful spasms. This condition is currently known by the gender neutral name *stiff person syndrome* (SPS). A focal variant of the disorder has been called the *stiff limb syndrome*.

Epidemiology

SPS occurs more often in women, but both men and women can be affected (average age of symptom onset is 35 years) and develop progressive symptoms over several months or years. SPS is quite rare and exact epidemiologic data is lacking; the estimated prevalence is one in a million. It is most often an immunologically mediated disorder with the presence of anti–glutamic acid decarboxylase-65 (anti-GAD65) antibodies; it may coexist with other autoimmune disorders including type 1 diabetes mellitus (in at least 35% of patients with SPS), Hashimoto thyroiditis, Graves disease, pernicious anemia, vitiligo, and celiac disease. A paraneoplastic form of SPS accounts for about 5% of cases most often associated with breast cancer but also reported with thyroid, renal, or colon cancer. The disorder is extremely rare in children; however, several case reports are available.

Pathobiology

CNS γ-aminobutyric acid (GABA)-secreting neurons play a major role in the normal inhibition of excessive continuous motor activation. GABA synthesis from glutamic acid is catalyzed by the enzyme glutamic acid decarboxylase (GAD). The discovery of antibodies against the 65-kDa GAD protein in most patients suggests immunologically mediated dysfunction of inhibitory synapses. **Figure 98.1** illustrates the inhibitory synapse and subcellular localization of antigenic targets of antibodies found in SPS. Reported association of SPS with autoimmune diseases as pernicious anemia, thyroid disease, type 1 diabetes mellitus, and others provides further support for the role of autoimmunity. The presence of anti-GAD65 antibodies with other neurologic disorders, including cerebellar ataxia (with or without coexisting SPS), epilepsy, or progressive encephalomyelitis with rigidity and myoclonus (PERM) suggests a spectrum of pathology associated with neuronal disinhibition in which SPS is one subtype. Although there is often an association of anti-GAD65 antibodies and SPS, the direct pathogenic role of anti-GAD65 antibodies remains uncertain. One major puzzle is that the antigenic GAD65 enzyme is intracellular and therefore supposedly hidden from the offensive antibodies. Furthermore, unlike myasthenia gravis, another antibody-mediated autoimmune disease where antibodies are directed against surface nicotinic acetylcholine receptors, passive transmission of antibodies (eg, in maternal placental transfer) does not confer the SPS. It has been suggested that CNS pathology is mediated by glutamic acid decarboxylase-specific $CD4^+$ T cells rather than the antibodies.

It may be that other associated antibodies are the pathologic culprits as, for example, the anti-GABA receptor–associated protein autoantibody. Dalmau and colleagues found that antibodies directed against the glycine receptor subunit alpha 1 (GlyRα1) immunoglobulin G antibodies are present in 12% of SPS patients and are found in other hyperexcitable disorders affecting brainstem and spinal cord, most often PERM. Anti-GlyRα1 antibodies may predict good response to immunotherapy. Mutations in the gene encoding the GlyRα1 cause *hyperekplexia* or *startle disease*.

Over the years, a paraneoplastic subgroup form of SPS patients was identified. Many of those patients were positive for autoantibodies directed against other molecules in the inhibitory synapse such as amphiphysin (breast and small cell lung cancer) and gephyrin (mediastinal cancer).

FIGURE 98.1 The neuronal inhibitory synapse. γ-Aminobutyric acid (GABA) and glycine are primary inhibitory neurotransmitters. Dysfunction of components of the synapse (presynaptic, synaptic, and postsynaptic) can lead to loss of inhibition and clinical stiffness and spasms. Abbreviations: BZD, benzodiazepine; GABARAP, GABA receptor–associated protein; GAD, glutamic acid decarboxylase.

Clinical Manifestations

Progressive stiffness and intermittent spasms of the axial musculature characterize the classic form of SPS, but distal limb muscles may also be affected. Aching discomfort and stiffness tend to predominate in the axial and proximal limb muscles, causing a hyperlordotic posture, with awkward gait and slowness of movements. Unlike tetanus, trismus does not occur, but facial and oropharyngeal muscles may be affected. In some cases, respiratory muscles are involved. The stiffness diminishes during sleep and under general anesthesia, differentiating it from other motor unit hyperexcitable syndromes such as neuromyotonia. The spasms may lead to joint deformities and are powerful enough to rupture muscles, rip surgical sutures, and fracture bones. Painful reflex spasms and falls occur in response to movement, sensory stimulation, or emotional changes. Fear of attacks elicited by environmental stimulation may lead to a debilitating avoidance of public places. Anxiety and task-specific phobias can be dominant features in SPS and may contribute to the often-observed delay in diagnosis or misdiagnosis notably because the spasms and rigidity improve with anxiety targeted treatment. Physical examination shows markedly increased axial and proximal muscle tone. However, strength, coordination, and sensation are preserved. Passive muscle stretch provokes an exaggerated reflex contraction that lasts several seconds. **Table 98.2** highlights the dominant features of classic SPS. The startle reactions of SPS are similar to those in hyperekplexia.

TABLE 98.2 Defining Characteristics of the Stiff Person Syndrome[a]

- Prodromal stiffness of axial muscles
- Slow progress to proximal limbs, walking awkward
- Fixed deformity of the spine, lordosis, "permanent shrug" (neck drawn down to shoulder girdle)
- Spasms precipitated by startle, jarring, noise, emotional upset
- Otherwise normal findings on motor and sensory examination
- Anxiety and task-specific phobias
- Normal intellect and affect
- Continuous motor activity in affected muscles relieved by intravenous or oral diazepam

[a]Modified from Lorish TR, Thorsteinsson G, Howard FM Jr. Stiff-man syndrome updated. *Mayo Clin Proc.* 1989;64(6):629-636.

FIGURE 98.2 Schematic depiction of simultaneous agonist/antagonist electromyography recordings in stiff person syndrome (SPS). The normal response tracings **(top)** show runs of agonist muscle motor unit action potentials associated with inhibition of motor unit action potentials in the antagonist and vice versa. In contrast, paired tracings recorded in a stiff person patient **(bottom pair)** show uninhibited simultaneous activation of both agonist and antagonist muscles.

Diagnosis

Laboratory Data

The diagnosis of SPS is aided by the presence of serum or cerebrospinal fluid antibodies against GAD65 in high titers (2,000 U/mL or more), which are found in approximately 80% of cases. Anti-GAD65 antibodies are supportive of the diagnosis of SPS but not specific; they are found in other neurologic disorders (including cerebellar ataxia, PERM, and Batten disease), and low titers are associated with other autoimmune diseases (up to 22% of persons with type 1 diabetes mellitus). Other autoantibodies present in SPS include anti-GABA receptor–associated protein in 65% of SPS cases, anti-GlyRα1 antibodies in up to 10% of cases, antiamphiphysin in up to 5% (found in paraneoplastic cases most commonly with breast cancer), and antigephyrin (found in one case of paraneoplastic SPS).

Electrophysiology

Electromyography (EMG) reveals continuous firing of normal motor unit action potentials even at rest. This excessive firing may be inhibited by administration of intravenous diazepam. Another hallmark of the SPS is cocontraction of agonist and antagonist muscles. Normally, contraction of an agonist muscle is associated with inhibition of the activity of the antagonist, but this is not so in SPS (Fig. 98.2).

Imaging

Magnetic resonance imaging of the brain and spinal cord is normal in SPS and are most useful in ruling out other pathologies. Brain magnetic resonance spectroscopy, however, shows a marked reduction of the inhibitory GABA neurotransmitter.

Treatment and Outcomes

Until the discovery of anti-GAD and other autoantibodies, GABA-enhancing medications were used both for diagnosis and symptomatic treatment. The realization that autoimmunity likely plays a role opened new diagnostic and treatment possibilities. Dalakas showed clear benefit for patients with SPS treated with intravenous immunoglobulin in a randomized, double-blind, placebo-controlled study involving 16 patients with SPS LEVEL 1.[1] Although most patients experience benefit after initial dose of intravenous immunoglobulin, many require repeat treatment to sustain response. Steroids and rituximab (antibodies directed against B cells) have not been shown to be effective.

Benzodiazepines are the mainstay for rigidity and spasms (as well as anxiety), and patients often require titration up to high doses; on average, 40 mg/d, but some require several hundred milligrams per day. Baclofen may be used as an adjunct, and doses of 60 to 100 mg/d may be required. Other medications that may be helpful are gabapentin (300-1,200 mg three times daily), pregabalin (50-100 mg three times daily), levetiracetam (500-1,500 mg twice daily), and, in refractory cases, dantrolene sodium (starting at 25 mg daily and titrating up to a maximum of 100 mg four times daily). Dantrolene should be used with caution and monitoring for cardiac side effects and hepatotoxicity. Some may respond to intrathecal baclofen. Dalakas and his group recently reported long-term follow-up of up to 8 years of a very large series of 57 SPS patients showing that SPS, especially when left untreated, is a progressive disorder leading to disability over time.

OTHER CENTRAL NERVOUS SYSTEM DISORDERS OF MUSCLE STIFFNESS

Common CNS disorders can show increased muscle tone. Stroke, multiple sclerosis, amyotrophic lateral sclerosis, and primary lateral sclerosis are examples where loss of normal inhibition of the motor system occurs. These relatively more common entities are discussed elsewhere in this book.

Although tetanus and tetany share a similar name and also some clinical features, they are entirely distinct. Tetanus is discussed in Chapter 66 and is only briefly mentioned here because of the pathogenic similarities to SPS at the inhibitory synapse. Tetanus is caused by the toxin tetanospasmin released from the bacteria *Clostridium tetani* in contaminated wounds. This toxin reaches nerve terminals and travels by retrograde axonal transport to reach inhibitory interneurons in the spinal cord and brainstem. Tetanospasmin prevents the release of GABA and glycine into the synapse, effectively blocking inhibitory neurotransmission in a similar mechanism to SPS. However, unlike SPS, tetanus has a predilection for the brainstem, possibly due to the shorter length of cranial nerve axons, eliciting distinct

features such as trismus and forceful satanic-like smile ("risus sardonicus"). Opisthotonic spasm of axial muscles may cause fractures and respiratory failure. Treatment includes respiratory support, antibiotics, antitoxin treatment, and muscle relaxants. Tetanus is best prevented by immunization, which is unfortunately unavailable in many developing countries. Risus sardonicus is also seen in strychnine intoxication with a similar mechanism of action; however, the clinical setting and toxin exposure set the two syndromes apart.

Tropical spastic paraparesis is caused by the human T-lymphotrophic virus 1 retrovirus and is prevalent in the adult population of the Caribbean islands. This infectious myelopathy primarily affects the thoracic spinal cord and is manifest by progressive spasticity and weakness, bladder dysfunction, and minor sensory symptoms. There are no current effective disease-modifying agents which alter the long term debilitating course. Corticosteroids, interferon-α and interferon-β, as well as other agents have been tried with limited success. Treatment is largely symptomatic and directed to relieve spasticity, painful muscle spasms, and loss of bladder control.

There are hereditary forms of spastic paraparesis, most notably the hereditary spastic paraplegias. These are clinically and genetically heterogeneous. Clinical syndromes may be "pure" if only manifesting as spasticity and weakness in the legs with bladder dysfunction or "complicated" if additional neurologic and systemic symptoms are present. These can be autosomal dominant, autosomal recessive, or X-linked and may be diagnosed genetically.

PERIPHERAL NERVE AND MUSCLE HYPEREXCITABILITY

Acquired Neuromyotonia (Isaac Syndrome)

Isaac first described this disorder as a state of "continuous muscle fiber activity." The invariable clinical manifestation is myokymia, visibly apparent constant muscle twitching likened to a bag of writhing worms. As a result of the continuous activity, patients may develop muscle cramps or abnormal postures of the limbs, which may be persistent or intermittent and are identical to carpal or pedal spasm.

Epidemiology

Neuromyotonia is a rare disorder; no specific information regarding incidence or prevalence is available. The acquired autoimmune forms can be seen in association with multiple other autoimmune diseases, either neurologic (such as myasthenia gravis) or systemic. Neuromyotonia is at times a paraneoplastic syndrome associated mainly with thymoma or small cell lung cancer but also with breast carcinoma or lymphoma.

Pathobiology

In the autoimmune form, neuromyotonia was first attributed to the presence of antibodies directed against voltage-gated potassium channels (VGKC). These channels are necessary to stabilize conduction at nodes of Ranvier, prevent repetitive firing, and maintain resting potential. Anti-VGKC complex antibodies were also found in some patients with limbic encephalitis and additionally in patients with the syndrome of benign fasciculations with cramps. This wide phenotypic spectrum associated with anti-VGKC was puzzling. However, advances in specific antibody identification have improved our understanding of the hyperexcitability syndromes and aided in clinical classification. More recent studies show that, rather than binding the potassium channel itself, the "anti-VGKC antibodies" bind antigenic neuronal targets of the macromolecular complex associated with the channel. The two main antigens are the leucine-rich glioma-inactivated protein 1 (LGI1) and contactin-associated protein-like 2 (CASPR2). Anti-LGI1 antibodies target CNS structures and are more commonly associated with limbic encephalitis. Anti-CASPR2 antibodies on the other hand, target both central and peripheral nervous tissue. They may be associated with neuromyotonia as well as the cramp-fasciculation syndrome, which may be a mild variant of Isaac syndrome. It is reasonable therefore to consider this spectrum of phenotypes under the umbrella of *autoimmune peripheral nerve hyperexcitability disorders*.

Clinical Manifestations

Isaac syndrome affects children, adolescents, or young adults and begins insidiously, progressing slowly for months or a few years. Symptoms most often begin in the distal arms and legs. Slow movement, clawing of the fingers, and toe walking are later joined by stiffness of proximal and axial muscles; occasionally, oropharyngeal or respiratory muscles are affected. The motor symptoms are often accompanied by the profuse sweating syndrome of hyperhidrosis. The stiffness and myokymia are seen at rest but, unlike SPS, continue in sleep and under general anesthesia. Voluntary contraction may induce a spasm that persists during attempted relaxation.

If patients develop higher cortical dysfunction manifest by sleep disorders, personality changes, and delirium, the condition is named the *Morvan syndrome*. The fixed postures of the limbs in Isaac syndrome can be simulated by the rare genetic Schwartz-Jampel syndrome (SJS). However, SJS is characterized by the additional features of a unique facial appearance (blepharophimosis), short stature, and bony abnormalities. In "ocular neuromyotonia," the limbs and cranial muscles are spared and the disorder is confined to one or more extraocular muscles.

Diagnosis

Antibodies reactive against the VGKC are detected in 30% to 40% of patients with Isaac syndrome and in 80% of those with coexisting thymoma but may also be seen at very low titers in asymptomatic people (2%). They may also be found in patients with painful small-fiber neuropathy. The prevalence of distinct antibodies to CASPR2 and LGI1 in this population is unknown. It is reasonable to perform a malignancy screening because 20% to 25% of patients with Isaac syndrome have an underlying malignancy (although the Isaac syndrome may precede malignancy by many years).

EMG shows characteristic findings. The EMG recorded from stiff muscles reveals prolonged myokymic or neuromyotonic discharges. In electrical myokymia, grouped fasciculations fire at rates up to 60 Hz and sound like marching soldiers. Myokymia may be found in the EMG of some individuals without any clinically visible twitching. Furthermore, myokymia is not restricted to Isaac syndrome; it may appear in other clinically distinct entities as postradiation neuropathy, multiple sclerosis, or after exposure to the Timber rattlesnake venom. In electrical *neuromyotonia*, on the other hand, continuous discharges occur at

rates of 150 to 300 Hz, tend to start or stop abruptly, and sound like a "NASCAR engine" or a "dive bomber." Voluntary effort triggers more intense discharges that persist during relaxation, accounting for the myotonia-like aftercontraction, but electrical myotonia is not found. In SJS, the more frequent EMG pattern is that of myotonic discharges, but there may be continuous motor activity with both myokymic and neuromyotonic discharges.

Treatment

The treatment of the peripheral nerve hyperexcitability disorders is multitiered. The muscle contraction symptoms are usually controlled with anticonvulsants as carbamazepine (200-1,200 mg daily in divided doses) or phenytoin (100-300 mg daily). Mexiletine may also be used at doses of 100 to 300 mg three times daily but with caution in patients at risk of cardiac arrhythmias (monitor for QTc prolongation) and can rarely cause hepatotoxicity. Plasmapheresis (three to five sessions every other day) and intravenous immunoglobulin therapy (2 g/kg over 4-5 d) are effective in some patients, and in the paraneoplastic group, treatment is directed primarily against the underlying cancer.

Tetany

Tetany is a clinical syndrome characterized by convulsions, paresthesia, prolonged spasms of limb muscles, or laryngospasm; it is accompanied by signs of hyperexcitability of peripheral nerves. Tetany occurs in patients with hypocalcemia, hypomagnesemia, or alkalosis. Hyperventilation may unmask latent hypocalcemic tetany, but respiratory alkalosis itself only rarely causes outright tetany.

Intense circumoral and digital paresthesia generally precede the typical carpopedal spasms, which consist of adduction and extension of the fingers, flexion of the metacarpophalangeal joints, and equinovarus postures of the feet. In severe cases, the spasms spread to the proximal and axial muscles, eventually causing opisthotonus. In all forms of tetany, the nerves are hyperexcitable, as manifested by the reactions to ischemia (Trousseau sign) or percussion (Chvostek sign). The spasms are owing to spontaneous firing of peripheral nerves, starting in the proximal portions of the longest nerves. EMG shows individual motor units discharging independently at a rate of 5 to 25 Hz (at times up to 300 Hz); each discharge consists of a group of two or more identical potentials.

The treatment of tetany consists of correcting the underlying metabolic disorder. Hypomagnesemia may lead to secondary hypocalcemia because it is necessary for the secretion of the parathormone. Therefore, treatment of tetany requires normal restoration of both.

Neuroleptic Malignant Syndrome and Malignant Hyperthermia

Acute diffuse symptoms of muscle stiffness maybe associated with exposure to neuroleptic medications that inhibit dopamine. The neuroleptic malignant syndrome (NMS) may be dramatic and life-threatening if not aggressively treated (see also Chapter 133). The syndrome comprises acute alteration of mental status, fever, autonomic dysfunction, and muscle breakdown with high serum levels of creatine kinase (CK). Muscle necrosis may release intracellular potassium and myoglobin into the serum; the resulting hyperkalemia may lead to cardiac arrhythmias and renal failure. An often overlooked cause of sudden dopamine loss with possible similar consequences may occur with abrupt discontinuation of dopaminergic medications used by patients with Parkinson disease. The mainstay treatment of NMS is supportive with body cooling, intravenous fluids, and respiratory support. Dopamine agonists such as bromocriptine (5-10 mg three to four times daily) and the potentially hepatotoxic muscle relaxant dantrolene may be helpful (start 25 mg daily, titrate up to 100 mg three to four times daily).

Another syndrome similar to NMS is seen in patients exposed to anesthetic agents causing the malignant hyperthermia syndrome. The most common offensive agents are the neuromuscular blocking agent succinylcholine and the inhaled general anesthetics like halothane, sevoflurane, and desflurane. High fever is the hallmark of the syndrome, but muscle stiffness, consequences of muscle breakdown ("rhabdomyolysis" or myoglobinuria), and cardiorespiratory collapse are virtually undistinguishable from NMS. Treatment is similar to that of NMS as well. Patients with the rare inherited myopathy central core disease have mutations in the ryanodine receptor RYR1 and are most susceptible to malignant hyperthermia syndrome.

Muscle Cramps

The common *muscle cramp* is a sudden, forceful, painful muscle contraction that lasts from a few seconds to several minutes. Muscle cramps are most often benign but can also accompany various neuromuscular disorders such as peripheral nerve hyperexcitability syndromes, lower motor neuron disease, medications, and myopathies (metabolic, mitochondrial, or dystrophic).

Epidemiology

Most adults have at least one episode of benign leg cramps during a lifetime, with no significant prevalence difference between men and women. In some populations, such as elderly veterans, up to 50% experience nocturnal leg cramps, as do 30% to 50% of pregnant women, worsening as pregnancy progresses. Most cramps occur only at night, some have both day and nighttime cramps, and a few have daytime-only cramps. In many, the attacks occur several times per week, and some experience daily cramps. Cramps are common in children with Charcot-Marie-Tooth disease and are a major source for discomfort in patients with amyotrophic lateral sclerosis. Frequent cramps tend to accompany hypothyroidism, uremia, profuse sweating or diarrhea, hemodialysis, electrolyte abnormalities, and hypoglycemia. Statins and diuretics may provoke cramps as well.

Pathobiology

A cramp often starts with fasciculations, after which the muscle becomes intermittently hard and knot-like as the involuntary contraction waxes and wanes, passing from one part of the muscle to another. Normally, when an α-motor neuron fires, acetylcholine is released into the neuromuscular junction, which then binds to and elicits an action potential in the muscle fiber. This action potential is then translated into contraction by release of calcium from the sarcoplasmic reticulum and the interaction of actin and myosin to cause muscle shortening (twitch or contraction). The process ends when calcium concentration decreases; both muscle contraction and relaxation require adenosine triphosphate. If calcium levels remain elevated, relaxation cannot occur. Stretch of the muscle spindle Ia fiber excites the motor neuron and also causes muscle contraction (monosynaptic muscle stretch reflex). Inhibition occurs within the spinal cord by inhibitory interneurons.

The neuroanatomic origin and propagation of cramps is a topic of ongoing debate, and both peripheral and central mechanisms are invoked. Cramps may result from hyperexcitability of the motor neurons (induced by afferent input) resulting in an autonomous positive feedback loop, implicating a spinal contribution. Cramps can be induced distal to a peripheral nerve block with electrical stimulation, and such cramps can be terminated by stretching the muscle, favoring a nerve terminal site of origin.

Clinical Manifestations

Muscle cramps are experienced as abrupt, painful spasms lasting seconds to minutes. Cramps may be provoked by a trivial movement or by voluntary contraction of a shortened muscle. They may occur during vigorous exercise but are more likely to occur after exercise ceases. Benign fasciculations or myokymia may be associated with frequent muscle cramps in apparently healthy people. The legs and in particular the calves are most often affected by cramps. Nocturnal cramps typically cause forceful flexion of the ankle and toes. However, cramps can affect almost any voluntary muscle.

Most people have cramps at some time, but a few people have inordinately frequent cramps, often accompanied by fasciculations. This syndrome of *benign fasciculations* is disproportionately more frequent among physicians and other medical workers because they are more likely to know the ominous implications of fasciculations for the diagnosis of motor neuron disease. However, motor neuron disease almost never starts with fasciculations alone. If neither weakness nor wasting is seen, motor neuron disease is essentially excluded. The syndrome of benign fasciculation has been reported many times with variations on the name.

True cramps must be distinguished from cramp-like muscle pain unaccompanied by spasm. The cramps of McArdle disease (myophosphorylase deficiency) occur during exercise due to the block of glycogen metabolism. Because no electrical activity is evident in the EMG during the painful shortening of muscle affected by McArdle disease, the term *contracture* is used. The origin of the contracture is not known, but depletion of adenosine triphosphate in muscle has long been suspected. Muscle breakdown is associated with myoglobinuria and elevated CK values in serum.

Mild dystrophinopathies, with little or no clinical weakness, may be manifested by exertional muscle pain and myoglobinuria. These symptoms have been referred to as *muscle cramps*, but actual muscle spasm has not been described in such cases; the pain may simply be a measure of muscle injury. The dystrophic and nondystrophic myotonic disorders are discussed elsewhere in this textbook.

Myalgia and cramps are believed to be especially common in *myoadenylate deaminase deficiency*, but because this condition is common in asymptomatic people (found in 1%-3% of all muscle biopsies), the association is difficult to confirm. Moreover, in affected families, the muscle enzyme deficiency and clinical symptoms are not well linked.

Diagnosis

The diagnosis of the common muscle cramp is essentially based on the clinical history. It is important to exclude underlying medical and neurologic causes for cramps. Routine laboratory testing for electrolytes and other underlying medical disorders can be performed as clinically indicated on a case-by-case basis. Tests may include complete blood cell count, metabolic panel, and CK.

Electrodiagnostic testing is useful in diagnosing an underlying peripheral nerve or muscle disorder as well as characterizing any abnormal spontaneous muscle activity. EMG of a cramp shows brief, periodic bursts of motor unit potentials discharging at a frequency of 200 to 300 Hz, appearing irregularly, and intermingling with similar discharges from adjacent motor units. Several foci within the same muscle may discharge independently. This electrical activity clearly arises within the lower motor neuron.

Treatment

Passive stretching of the affected muscle usually terminates a cramp. However, a 2010 analysis by the American Academy of Neurology found insufficient evidence for nonpharmacologic treatment (such as stretching and hydration) of muscle cramps LEVEL 1.[2]

A Cochrane Review in 2010 found that the administration of quinine derivatives at doses of 200 to 500 mg per day were effective, although modestly, with few serious adverse events LEVEL 1.[3] Rare but serious adverse effects of quinine include thrombocytopenia, bleeding diathesis, cardiac arrhythmias, and acute hypersensitivity reactions, which may occur in 2% to 4% of persons treated. Other serious adverse effects include hypoglycemia, vision loss, psychosis, tinnitus, and esophagitis. Given the adverse effect profile, the U.S. Food and Drug Administration has issued multiple warnings, and both the U.S. Food and Drug Administration and American Academy of Neurology recommend against the use of quinine for the routine treatment of muscle cramps. Use of quinine is recommended only when cramps are disabling, not relieved by other agents, and with full patient education and monitoring for possibly serious side effects LEVEL 1.[1]

Despite the frequency of common cramps, no other agents have been sufficiently studied, but agents that may be effective for cramps include vitamin B complex (thiamine 50 mg, cobalamin 250 μg, pyridoxine 30 mg, riboflavin 5 mg), naftidrofuryl (not available in the United States; 100 mg 3 times daily), and diltiazem (30 mg daily). Other agents commonly used with variable success include baclofen, benzodiazepines, carbamazepine, oxcarbazepine, verapamil, magnesium citrate, and gabapentin; however, evidence is insufficient regarding these agents. For cramps associated with hemodialysis, vitamin E and C may be effective, and zinc sulfate and branched chain amino acids may be helpful in cramps associated with cirrhosis. For cramps occurring in association with amyotrophic lateral sclerosis, gabapentin and tetrahydrocannabinol are ineffective.

Outcome

The common muscle cramp has a good prognosis, but pain and discomfort can be troublesome. Nocturnal cramps can interrupt sleep.

99 Metabolic and Mitochondrial Myopathies in Adults

Michio Hirano, H. Orhan Akman, and Salvatore DiMauro

KEY POINTS

1. Metabolic myopathies encompass a clinically and etiologically diverse group of rare inherited disorders due to defects in cellular energy metabolism, including the breakdown of carbohydrates and fatty acids to generate adenosine triphosphate, predominantly through mitochondrial respiratory chain oxidative phosphorylation.
2. Adult glycogen storage disorders can present as slowly progressive myopathies (eg, acid maltase deficiency) or as acute muscle cramps with or without myoglobinuria after short bursts of intense exercise.
3. Myopathies due to fatty acid oxidation defects often present with myalgias, fatigue, and myoglobinuria, typically without cramps, after prolonged exercise.
4. Mitochondrial disease due to primary defects of oxidative-phosphorylation can present as isolated myopathies often with extraocular muscle weakness and exercise intolerance disproportionate to the level of muscle weakness.

INTRODUCTION

Metabolic myopathies comprise a clinically and etiologically diverse group of disorders due to defects in cellular energy metabolism, including the breakdown of carbohydrates and fatty acids to generate adenosine triphosphate (ATP), predominantly through mitochondrial respiratory chain oxidative phosphorylation. Accordingly, metabolic myopathies can be etiologically classified into three broad categories: glycogen storage diseases, fatty acid oxidation disorders, and mitochondrial diseases. These metabolic myopathies present with a clinical spectrum ranging from severe infantile-onset multisystemic diseases to mild adult-onset isolated myopathies. In this chapter, we focus on metabolic myopathies that affect adults.

EPIDEMIOLOGY

Metabolic myopathies are rare diseases. The most common of these disorders is Pompe (acid maltase deficiency) disease with variable ethnic and geographic incidence at newborn screening from 1:4,400 births annually in Austria to 1:165,000 in people in New York State. Prevalence of late-onset Pompe disease has been estimated to be 1:60,000. Other frequent metabolic myopathies include McArdle disease (myophosphorylase deficiency) and carnitine palmitoyltransferase II (CPT II) deficiency. The prevalence of McArdle disease has been estimated to be 1:100,000 in the Dallas–Fort Worth, Texas, region and a minimum of 1:170,000 in Spain. The prevalence of CPT II deficiency is unknown; however, over 300 patients have been reported. Although individual mitochondrial diseases are rare, collectively, the prevalence of mitochondrial disorders in adults is approximately 1:4,300.

PATHOBIOLOGY

Energy in the form of ATP is required to drive numerous cellular functions including muscle contraction. The main fuels used to generate ATP are glycogen, glucose, and free fatty acids. Glycogen is metabolized in the cytoplasm to pyruvate, which enters mitochondria (Fig. 99.1). Short- and medium-chain fatty acids cross freely into the mitochondria, whereas long-chain fatty acids require binding to carnitine for transport across the mitochondrial membrane, a process mediated by carnitine-acylcarnitine translocase and CPTs I and II (Fig. 99.2). Once in the mitochondria, all these substrates are converted into acetyl-coenzyme A (CoA), which feeds into the Krebs cycle. In this critical cycle, reducing equivalents (electrons) combined with protons are bound to intermediate molecules, nicotinamide adenine dinucleotide and flavin adenine dinucleotide, reduced, which deliver the electrons to the mitochondrial respiratory chain to produce ATP and water.

Defects in any of these pathways—glycogen catabolism (glycogenolysis and glycolysis), fatty acid oxidation, Krebs cycle, and mitochondrial respiratory chain and oxidative phosphorylation—cause human disorders that often predominantly affect muscle due to its high energy requirements, particularly during exercise. Because most of the enzyme defects are partial, many of these diseases manifest in adulthood with muscle symptoms either in isolation or with other clinical features.

Abundant glucose is stored in liver and skeletal muscle in the form of a polysaccharide called *glycogen*. The glycogenoses include disorders characterized by genetic mutations in glycogen synthesis (glyconeogenesis), degradation (glycogenolysis), or glucose degradation (glycolysis). To date, 15 glycogenoses have been identified (see Fig. 99.1); most are autosomal recessive except for phosphoglycerate kinase (PGK) and phosphorylase *b* kinase deficiency, which are X-linked.

Fatty acids are the primary energy source for muscle at rest and during periods of prolonged low-intensity exercise. Fatty acids are catabolized by the β-oxidation enzymes, which cleave two-carbon fragments with each cycle. Thus, lipidoses arise due to failure of fatty acid transport into mitochondria secondary

FIGURE 99.1 Scheme of glycogen metabolism and glycolysis. Roman numerals denote muscle glycogenoses due to defects in the following enzymes: 0, glycogen synthase; II, acid maltase; III, debrancher; IV, brancher; V, myophosphorylase; VII, phosphofructokinase; VIII, phosphorylase *b* kinase; IX, phosphoglycerate kinase; X, phosphoglycerate mutase; XI, lactate dehydrogenase; XII, aldolase; XIII, β-enolase; XIV, phosphoglucomutase 1; and XV, glycogenin-1. Red numerals designate glycogenoses associated with exercise intolerance, cramps, and myoglobinuria. Blue italic numerals correspond to glycogenoses causing weakness. Abbreviations: ADP, adenosine diphosphate; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; PLD, phosphorylase-limit dextra; UDPG, uridine diphosphate glucose.

to carnitine or CPT I or II deficiencies or to defects of intramitochondrial β-oxidation. These disorders are inherited as autosomal recessive traits. The more severe variants present in infancy or childhood with primary involvement of liver or brain, whereas the milder adult forms are predominantly myopathic and include the myopathic variant of CPT II deficiency, trifunctional protein (TFP) deficiency, and very long chain acyl-CoA dehydrogenase (VLCAD) deficiency.

In addition to catabolizing lipids, mitochondria perform additional essential functions including Krebs cycle and amino acid metabolism as well as energy production through the respiratory chain and oxidative phosphorylation. The respiratory chain is composed of four multisubunit enzymatic complexes (I, II, III, and IV), which generate a proton gradient across the inner mitochondrial membrane that, in turn, drives ATP synthesis by complex V. In addition, coenzyme Q_{10} (CoQ_{10}) and cytochrome *c* are critical components of the mitochondrial respiratory chain, serving as "electron shuttles" between the complexes. Originally restricted to primary defects of the respiratory chain and oxidative phosphorylation, mitochondrial diseases have expanded to encompass defects of mitochondrial transcription, translation, mitochondrial DNA maintenance, protein importation, lipid membranes, and organellar dynamics (fusion, fission, and movement) (see Chapter 144).

DIAGNOSIS

From a clinical point of view, metabolic myopathies can be categorized into two different groups: (1) those that show symptoms and signs related to exercise (exercise intolerance, cramps, myalgias, myoglobinuria) with normal interictal examination and (2) those with fixed symptoms such as muscle weakness often associated with systemic involvement (such as encephalopathies or endocrinopathies). When evaluating a patient with exercise-related symptoms, clinicians should ask two questions: (1) What type of exercise provokes symptoms? (2) Are there associated triggering factors? If short bursts of high-intensity exercise cause muscle cramps or myoglobinuria, the patient may have a defect of glycogen metabolism. Examples of this type of activity include weight lifting or sprinting. In young patients who play baseball or softball, the "home run" sign (Haller sign), inability to sprint around the bases due to exercise-induced muscle spasms, is a typical complaint in patients with glycogenoses, such as McArdle disease. In contrast, if the patient complains that prolonged exercise (such as hiking or playing soccer) triggers myalgias, fatigue, and myoglobinuria without acute contractures, the patient is likely to have a defect of fatty acid oxidation. The symptoms often occur when the patient is fasting or under stress. A prototypical example is a young adult

FIGURE 99.2 Schematic representation of mitochondrial metabolism. Abbreviations: ADP, adenosine diphosphate; ATP, adenosine triphosphate; CoA, coenzyme A; CoQ, coenzyme Q; CPT, carnitine palmitoyltransferase; Cyt c, cytochrome c; ETF DH, electron transfer flavoprotein dehydrogenase; ETF ox, electron transfer flavoprotein oxidized and reduced; ETF red, electron transfer flavoprotein and reduced; $FADH_2$, flavin adenine dinucleotide, reduced; NADH, nicotinamide adenine dinucleotide; PDHC, pyruvate dehydrogenase complex; TFP, trifunctional protein; VLCAD, very long chain acyl-CoA dehydrogenase.

with CPT II deficiency who enlists in military service and has difficulty completing long marches due to fatigue and myalgias followed by myoglobinuria.

In the past, the term *myoglobinuria* was reserved for grossly pigmented urine, but modern techniques can detect amounts of this protein so minute that discoloration may not be evident. (Determination of serum myoglobin content by radioimmunoassay has similar diagnostic significance as measurement of serum creatine kinase [CK] activity.) The clinically important syndromes, however, are associated with gross pigmenturia. Numerous conditions cause myoglobinuria (Table 99.1). Sometimes, the disorder can be recognized without direct demonstration of myoglobin in the urine: For instance, acute renal failure in a patient with levels of serum CK activity over 20,000 U/L would indicate myoglobinuric renal failure. Inexplicably, the cumbersome neologism *rhabdomyolysis* was favored for many years, but a 2020 PubMed search revealed that "myoglobinuria" is holding fast. Myoglobin is the visible pigment in the urine, and it is a toxin that contributes to kidney injury; the syndrome originates with muscle necrosis (rhabdomyolysis) and does not need a new and imprecise name.

Disorders of Glycogen Metabolism (Glycogenoses)

Some patients with glycolytic, lipid, or mitochondrial disorders can develop isolated progressive myopathy and persistent weakness. More typically, patients with mitochondrial diseases can show a wide range of extramuscular manifestations. In this section, general clinical aspects of these metabolic myopathies with emphasis on the more common forms are described.

Clinical presentations of muscle glycogenoses are protean, ranging from profound multisystem disease in infancy to exercise intolerance or isolated progressive muscle weakness in adults. Here, we focus on the adult patients. Myophosphorylase deficiency (McArdle disease, glycogenosis type V) is a prototypical glycogenolytic disorder with episodic muscle dysfunction and myoglobinuria. It is the most common disorder of skeletal muscle

TABLE 99.1 Classification of Human Myoglobinuria

Hereditary Myoglobinuria
Disorders of Glycogen Metabolism
Myophosphorylase deficiency (McArdle [1951]; MIM 232600)
Phosphofructokinase deficiency (Tarui et al [1965]; MIM 171840)
Phosphoglycerate kinase (MIM 311800)
Phosphoglycerate mutase (MIM 261670)
Lactate dehydrogenase (Kanno et al [1980]; MIM 150000)
Disorders of Lipid Metabolism
Carnitine palmitoyltransferase II deficiency (DiMauro & DiMauro-Melis [1973]; MIM 255110)
LPIN1 mutations (MIM 268200)
VLCAD deficiency (MIM 201375)
Trifunctional protein deficiency (MIM 609015)
Mitochondrial Myopathies
Mitochondrial DNA (MTCYB) mutations
Coenzyme Q_{10} deficiency
Other Genetic Myopathies
RYR1 deficiency (with malignant hyperthermia MIM 145600, without malignant hyperthermia MIM 117000 and 255320)
Becker/Duchenne muscular dystrophy
FSHD
Limb-girdle muscular dystrophy 1C (Caveolin deficiency)
Limb-girdle muscular dystrophy 2C (SGCG, γ-sarcoglycan deficiency)
Limb-girdle muscular dystrophy 2D (SGCA, α-sarcoglycan deficiency)
Limb-girdle muscular dystrophy 2E (SGCB, β-sarcoglycan deficiency)
Limb-girdle muscular dystrophy 2I (FKRP deficiency)
Limb-girdle muscular dystrophy 2L (ANO5 mutations)
Sporadic Myoglobinuria
Exertion in Untrained Individuals
"Squat-jump" and related syndromes
Anterior tibial syndrome
Convulsions
High-voltage electric shock, lightning stroke
Agitated delirium, restraints
Status asthmaticus
Prolonged myoclonus or acute dystonia
Crush Syndrome
Compression by fallen weights
Compression by body in prolonged coma

Sporadic Myoglobinuria
Ischemia
Arterial occlusion
Cardioversion
Coagulopathy in sickle cell disease or disseminated intravascular coagulation
Ischemia in compression and anterior tibial syndromes
Laparoscopic nephrectomy
Ligation of vena cava
Surgery on morbidly obese people, including bariatric surgery
Metabolic Depression
Barbiturate, carbon monoxide, narcotic coma
Cold exposure
Diabetic acidosis
General anesthesia
Hyperglycemic, hyperosmolar coma
Hypothermia
Exogenous Toxins and Drugs
Alcohol abuse
Amphotericin B
Carbenoxolone
Clopidogrel (and heart transplant)
Gemfibrozil (plus statin)
Glycyrrhizae
Haff disease
Heatstroke
Heroin
Hypokalemia, chronic, any cause
Interferon α-2b
Isotretinoin
Malayan sea-snake bite poison
Malignant neuroleptic syndrome
Plasmocid
Phenylpropanolamine
Statin drugs
Succinylcholine
Toxic shock syndrome
Viral infection (CMV, influenza, others)
Wasp stings
Progressive Muscle Disease
Alcoholic myopathy
Polymyositis or dermatomyositis
Cause unknown

Abbreviations: CMV, cytomegalovirus; FSHD, fascioscapulohumeral dystrophy; VLCAD, very long chain acyl-coenzyme A dehydrogenase.

carbohydrate metabolism and one of most frequent genetic myopathies. Patients with McArdle disease typically exhibit intolerance to static or isometric muscle contractions and also to dynamic exercise that can trigger episodes of reversible "muscle crises." Acute crises manifest mainly in the form of premature fatigue and contractures, frequently accompanied by muscle breakdown (rhabdomyolysis) with elevated serum CK and sometimes by myoglobinuria. In addition to McArdle disease, six other forms of glycogenoses manifest exercise-induced myoglobinuria: type VII (phosphofructokinase [PFK] deficiency, Tarui disease), type VIII (phosphorylase *b* kinase), type IX (PGK deficiency), type X (phosphoglycerate mutase [PGAM] deficiency), type XI (lactate dehydrogenase deficiency), and type XIV (phosphoglucomutase 1 deficiency).

Another important sign considered pathognomonic is the "second wind," which is a marked improvement in exercise tolerance about 10 minutes into aerobic exercise involving large muscle masses (jogging or cycling). The second wind, as manifested by a marked decrease in early exertional tachycardia (eg, a decrease from ~140-150 beats per minute to ~120 beats per minute) starting after around 7 minutes of exercise, does not occur in patients with other disorders that are also associated with exercise intolerance, such as PFK deficiency and other glycogenoses, mitochondrial myopathies, or disorders of lipid metabolism. This phenomenon is due to increased uptake of glucose and use of fatty acid.

Hemolytic anemia (elevated indirect bilirubin and reticulocytes) is seen in glycogenosis due to defects in genes partially expressed in erythrocytes such as PFK, PGK, and aldolase A. Cognitive deficits are often associated with the adult polyglucosan body disease (APBD) form of branching enzyme deficiency (type IV) and PGK deficiency.

Acid maltase or acid α–glucosidase (GAA) is an enzyme responsible for the catabolism of glycogen within lysosomes. Infantile-onset acid maltase deficiency (type II, Pompe disease) presents as a myopathy and cardiomyopathy, which, if untreated, is typically fatal in the first year of life. In contrast, in the late-onset form of Pompe disease beginning in childhood through adulthood, patients have slowly progressive fixed proximal muscle weakness and early respiratory insufficiency. Although myopathy is the predominant manifestation, patients with Pompe disease also develop basilar artery and aortic aneurysms, bladder or bowel incontinence, and dysphagia. An autopsy study of a late-onset Pompe patient revealed ultrastructural abnormalities in the smooth muscle of blood vessels, gastrointestinal tract, and bladder, thereby accounting for the extraskeletal muscle manifestations. Hearing loss has also been reported in this disease. It is important to diagnose Pompe disease because enzyme replacement therapy with recombinant human GAA (rhGAA) dramatically improves the cardiomyopathy in the infantile form and less effectively improves the myopathy in both infantile and late-onset forms.

In other cases, such as debrancher deficiency (type III, Cori-Forbes disease), distal muscle weakness can be combined with cardiomyopathy and peripheral neuropathy in patients who had shown in infancy hepatomegaly, hypoglycemia, and failure to thrive, all of which usually improve around puberty. Thus, adult patients with debrancher deficiency can manifest distal muscle weakness and wasting with electromyographic myogenic and neurogenic abnormalities.

Branching enzyme deficiency (type IV) presents with heterogeneous phenotypes ranging from congenital or infantile neuromuscular disorders to late-onset APBD, which manifests as progressive upper and lower motor neuron dysfunction, stocking-glove sensory loss, bladder dysfunction, and dementia. Muscle and nerve biopsies of APBD patients reveal periodic acid-Schiff–positive but diastase-resistant polyglucosan bodies. Although reported in various ethnic groups, APBD is particularly frequent in the Ashkenazi Jewish population due to founder mutations. Polyglucosan bodies are also characteristic of a juvenile-onset myopathy often accompanied by cardiomyopathy due to mutations in *RBCK1*, which encodes a ubiquitin ligase.

Striking absence of glycogen is characteristic of two disorders: glycogenosis type 0, glycogen synthase (GS1) deficiency, and glycogenosis type XV, glycogenin-1 deficiency. Both enzymes are required for the synthesis of glycogen. GS1 deficiency has presented as childhood exercise intolerance, cardiomyopathy, sudden death, or cardiomyopathy and myopathy. Glycogenin-1 deficiency has been associated with two phenotypes: a late adult-onset pure skeletal myopathy and young adult-onset myopathy with cardiomyopathy; muscle biopsies have polyglucosan bodies.

Disorders of Lipid Metabolism

Since DiMauro and DiMauro-Melis described the first patients with CPT II deficiency, this disease has been the most frequently diagnosed disorder of lipid metabolism. The first symptoms most often occur between 6 and 20 years of age, but age at onset may be older than 50 years. The symptomatology usually consists of recurrent attacks of myalgias and muscle stiffness or weakness, often associated with myoglobinuria. The attacks are usually acute and the consequences may be prolonged up to several weeks. The patients are usually asymptomatic between attacks. The frequency of these attacks is highly variable. The rhabdomyolysis may occasionally be complicated by two types of life-threatening events: more commonly, acute renal failure secondary to myoglobinuria and, much less frequently, respiratory insufficiency secondary to respiratory muscle involvement. Symptoms are usually prompted by prolonged exercise and less commonly by prolonged fasting, high-fat intake, exposure to cold, mild infection (especially in children), fever, emotional stress, general anesthesia, or drugs such as diazepam or ibuprofen. In all cases, the clinical symptomatology is restricted to skeletal muscle without liver or heart involvement.

Defects of most β-oxidation enzymes typically manifest in infancy with severe multisystem disease; however, the clinical presentation of VLCAD deficiency may be indistinguishable from CPT II deficiency. Trifunctional enzyme catalyzes three steps in long-chain fatty acid β-oxidation: enoyl-CoA hydratase, long-chain 3-hydroxyacyl-CoA dehydrogenase, and acylthiolase (see **Fig. 99.2**). Adults with TFP deficiency present with recurrent rhabdomyolysis triggered by prolonged exercise, fasting, or infections similar to CPT II and VLCAD deficiencies; however, TFP mutations are often associated with peripheral neuropathy and pigmentary retinopathy.

Multiple acyl-CoA dehydrogenation deficiency (MADD), also known as *glutaric aciduria type II*, is an autosomal recessive disorder due to mutations in genes encoding either one of the two subunits of the electron transferring flavoprotein (*ETFA* and *ETFB*) or to mutations in the gene encoding the electron transfer flavoprotein dehydrogenase (*ETFDH*) and resulting in abnormal fatty acid, amino acid, and choline metabolism. Less severely affected patients might present with progressive muscle weakness

and lipid storage myopathies with secondary muscle CoQ_{10} deficiency, mainly in adulthood and are sometimes responsive to riboflavin treatment (riboflavin responsive MADD), CoQ_{10} supplementation, or both.

The myopathic form of CoQ_{10} deficiency is characterized by proximal myopathy with premature fatigue, weakness, and increased serum levels of CK and lactate. Muscle biopsies show excessive numbers of lipid droplets, predominantly in type 1 fibers, combined deficiency of respiratory chain complexes I and III, and CoQ_{10} levels below 50% of normal. Mutations in the *ETFDH* gene, leading to a decrement in complex electron transfer flavoprotein-ubiquinone oxidoreductase (ETF:QO) activity, have been identified in adult-onset MADD and some cases of myopathy with CoQ_{10} deficiency indicating that they can be allelic diseases.

Neutral lipid storage disease (NLSD) present with mild to moderate proximal limb weakness with striking accumulation of lipid in skeletal muscle and other tissues as well as in leukocytes (Jordan anomaly). CK is persistently elevated and has preceded weakness. Mutations in *PNPLA2* encoding adipocyte triglyceride lipase cause neutral lipid storage myopathy, whereas mutations in *ABHD5*, which encodes CGI-58 (activator of adipocyte triglyceride lipase), cause lipid storage myopathy with ichthyosis (Chanarin-Dorfman syndrome).

Mitochondrial Diseases

Although mitochondrial diseases frequently present as infantile- or childhood-onset multisystemic diseases, many adult patients have myopathy as the predominant or only manifestation with either fixed weakness, exercise intolerance, or both. Myoglobinuria is less common in respiratory chain oxidative phosphorylation disorders relative to other metabolic myopathies.

Like most myopathies, mitochondrial myopathies cause proximal limb weakness, but extraocular muscles are also frequently affected, leading to ptosis and chronic progressive external ophthalmoplegia (CPEO). CPEO begins in childhood or adulthood and typically manifests with symmetric and slowly progressive impairment of eye movements accompanied by ptosis. Occasionally, the extraocular muscle weakness can be strikingly asymmetric. CPEO is sometimes misdiagnosed as myasthenia gravis; however, fixed weakness with minimal or no fluctuations, absence of acetylcholine receptor and muscle specific tyrosine kinase antibodies, as well as absence of neuromuscular junction dysfunction on electrophysiologic studies should lead clinicians to screen for myopathies such as CPEO.

CPEO often remains a pure myopathy with limb weakness and variable dysphagia and respiratory muscle involvement. In contrast, CPEO can be part of a multisystemic disease such as Kearns-Sayre syndrome (KSS) or sensory ataxic neuropathy dysarthria ophthalmoplegia (SANDO) (see Chapter 144). Some individuals are classified as CPEO-plus because they develop additional neurologic manifestations but lack features to fulfill criteria for KSS, SANDO, or other defined clinical syndromes. CPEO can be due to maternally inherited mitochondrial DNA (mtDNA) point mutations, sporadic single large-scale deletions of mtDNA, or primary autosomal dominant or recessive mutations that cause secondary multiple deletions of mtDNA.

In patients with mitochondrial myopathies, exercise intolerance presents with premature fatigue with activities as mild as walking up a single flight of stairs. After a short rest, patients usually can resume their activity but symptoms recur. Mitochondrial disease patients often report subjective heaviness or burning of muscles with exertion but, in contrast to patients with glycogenoses, do not typically manifest stiffness, cramps, or second wind phenomenon. The exercise intolerance is often disproportionately severe relative to muscle weakness. This symptom can be isolated or associated with muscle weakness and multisystemic involvement. Exercise testing is particularly helpful as an evaluation and screening tool in mitochondrial myopathies. Elevated lactate levels at rest and exaggerated lactate responses after even trivial exercise are useful clues to the diagnosis of mitochondrial disease. One of the hallmarks of mitochondrial myopathies is a reduction in maximal whole-body oxygen consumption (VO_2 max) demonstrated by a characteristic deficit in peripheral oxygen extraction (arteriovenous oxygen difference) and an enhanced oxygen delivery (hyperkinetic circulation). Alternatively, in specialized referral centers, phosphorus-31 nuclear magnetic resonance spectroscopy can reveal prolonged recovery of levels of high-energy phosphate compounds (eg, ATP and phosphocreatine) after exercise in patients with mitochondrial myopathies.

An unusual group of mitochondrial disease patients present with sporadic isolated myopathies with exercise intolerance variably accompanied by proximal muscle weakness and myoglobinuria. It is important for clinicians to be aware of this condition, which in several cases, was misdiagnosed as chronic fatigue syndrome or fibromyalgia. Resting venous lactic acid is elevated in most patients with this condition; therefore, blood lactate is a useful noninvasive screening test for this syndrome. In most cases, muscle biopsies reveal ragged-red fibers that are cytochrome *c* oxidase–positive because the gene defect is often a mutation in the cytochrome *b* gene, which encodes a subunit of complex III, or in an ND gene, encoding a subunit of complex I. In addition, other mutations in mtDNA have been associated with exercise intolerance, including transfer RNA (tRNA) mutations as well as mutations in protein coding genes for subunits of respiratory chain complex I or IV. Because the mutations are not detectable in blood in most of these patients, muscle biopsy is generally required to make the diagnosis.

A rare clinical form of CoQ_{10} deficiency presents as encephalomyopathy in childhood with the triad of encephalopathy (seizures, mental retardation, or ataxia), muscle weakness often with myoglobinuria, and ragged-red fibers in muscle. Patients have been diagnosed in adolescence or adulthood and have improved with CoQ_{10} supplementation.

A rare childhood-onset mitochondrial myopathy has been identified in Northern Swedish patients who have exercise intolerance. In these patients, modest exercise triggers fatigue, tachycardia, shortness of breath, and myoglobinuria due to a founder splice site mutation in *ISCU*, which encodes the iron-sulfur scaffold protein required by iron-sulfur subunit containing enzymes such as aconitase and complexes I, II, and III of the mitochondrial respiratory chain.

Approach to Diagnostic Testing

The diagnosis of glycogenosis should be considered in patients with recurrent myoglobinuria triggered by brief intense exercise. Presence of the "second wind" is indicative of McArdle disease (myophosphorylase deficiency), whereas in adults, signs of hemolytic anemia with elevated uric acid (and occasionally gout) is suggestive of PFK or PGK deficiency in adults. The specific glycolytic defect can be identified by sequencing blood DNA or by measuring biochemical activity of seven glycolytic enzymes

(myophosphorylase, PFK, phosphorylase *b* kinase, phosphoglycerate kinase, PGAM, lactate dehydrogenase, and phosphoglucomutase 1). In patients with limb weakness, early respiratory muscle involvement, and electromyography evidence of prominent spontaneous activity of paraspinal muscles, the diagnosis of Pompe disease should be considered. A dried blood spot test can detect acid maltase deficiency. Definitive diagnosis is made by sequencing *GAA* or by a muscle biopsy showing increased membrane-bound glycogen with markedly reduced acid maltase activity. Debrancher enzyme deficiency should be considered in patients with fixed distal greater than proximal limb weakness with electromyography myogenic and neurogenic abnormalities and visceral organ involvement. Branching enzyme deficiency is clinically recognizable by the combination of upper and lower motor neuron dysfunction, sensorimotor neuropathy, sphincter dysfunction, and dementia. Both debrancher and branching enzyme deficiencies can be diagnosed by DNA sequencing. In many cases, muscle histology showing excessive free glycogen lead to the diagnosis of debrancher deficiency, whereas detection of polyglucosan bodies is indicative of APBD. Detecting biochemical defects of muscle debrancher or branching enzyme is diagnostic, particularly in cases when DNA sequencing reveals variants of uncertain significance.

In patients with recurrent myoglobinuria triggered by prolonged exercise, fasting, or both, defects of fatty acid oxidation should be considered. Acylcarnitine profile may reveal elevated acylcarnitines (eg, long-chain acylcarnitines in CPT II and VLCAD deficiencies), particularly after overnight fasting; however, the profiles are often normal. The diagnosis can be made by blood DNA testing. CPT II activity can be measured in skeletal muscle or cultured fibroblasts.

In patients with suspected mitochondrial myopathy, measurement of free-flowing blood lactate and pyruvate can be useful; elevated resting lactate especially when the lactate-to-pyruvate ratio is high (ie, >20:1) is indicative of a mitochondrial respiratory chain oxidative phosphorylation defect. In patients with evidence of maternal inheritance, whole mtDNA sequencing offers a cost-effective approach to identifying mtDNA point mutations. Individuals with sporadic CPEO, CPEO-plus, or KSS should be screened for single large-scale mtDNA deletions, which are usually undetectable in blood and occasionally identified in urine sediment or buccal swabs but most reliably detected in muscle biopsies. In patients with autosomal CPEO, CPEO-plus, and SANDO, sequencing of nuclear genes, particularly *POLG* encoding the mtDNA polymerase catalytic subunit, can reveal the causative mutation(s). If blood and urine DNA screening is negative or ambiguous, muscle biopsy for histology, measurement of mitochondrial respiratory chain activities, and potential molecular genetic testing (eg, screening for mtDNA deletions or depletion) are often useful.

Although not a metabolic disorder, mutations in *RYR1* encoding the skeletal muscle ryanodine receptor are frequent causes of recurrent exercise-induced myoglobinuria. Heat, and to a lesser degree, viral infections, alcohol, and drugs can trigger episodes of myoglobinuria.

MANAGEMENT

Treatment of metabolic myopathies is limited. Enzyme replacement therapy for Pompe disease is the only disease-modifying therapy; however, efficacy is limited in adults. There is level 1 evidence of mild beneficial effects of enzyme replacement therapy on respiratory function and ambulation in patients with late-onset Pompe disease LEVEL 1.[1] Avoidance of precipitating factors (eg, intense exercise in patients with myoglobinuria due to glycogenesis) is critical.

Glucose or sucrose intake before exercise exacerbates muscle's symptoms (out-of-wind phenomenon) in PFK deficiency where the metabolic block occurs below the entry of glucose into glycolysis, whereas in McArdle disease, sugar intake ameliorates symptoms because the metabolic block is upstream of glucose catabolism. In other cases, such as PGAM or PFK deficiencies, this intervention does not produce changes in the exercise performance.

In patients with fatty acid oxidation disorders, a carbohydrate-rich diet and avoidance of fasting is often beneficial. In patients with CPT II, VLCAD, and TFP deficiencies, supplementation with medium-chain triglycerides can be beneficial.

For patients with mitochondrial myopathies, symptomatic therapy is important. Patients with severe ptosis that impairs vision, scleral contact lenses, eyelid crutches, or eyelid slings can be beneficial. Screening for heart block in patients with KSS or CPEO is important because timely placement of a pacemaker can be lifesaving. Aerobic exercise training improves oxidative capacity in patients with heteroplasmic mtDNA mutations.

OUTCOME

The long-term prognosis of patients with metabolic myopathies due to defects of glycogen or lipid metabolism is generally favorable. In patients with severe myoglobinuria, compartment syndrome and renal failure are serious complications that must be treated aggressively. In patients with recurrent myoglobinuria due to myophosphorylase or PFK deficiency, moderate fixed weakness often develops late in life. In contrast, patients with late-onset Pompe disease can develop severe restrictive lung disease that is amenable to bilevel positive airway pressure support.

The prognosis for patients with mitochondrial myopathies is variable. Patients with CPEO can have a very benign outcome with moderate to severe extraocular weakness as the main problem; however, some patients with CPEO have developed symptomatic dysphagia, restrictive lung disease, and marked limb weakness. Patients with KSS, SANDO, and other multisystemic mitochondrial diseases frequently progress and can develop severe encephalopathies and in the case of KSS, severe cardiomyopathy or visceral organ dysfunction that can be fatal in early to mid adulthood.

Gliomas 100

J. Ricardo McFaline-Figueroa and Patrick Y. Wen

KEY POINTS

1. Gliomas comprise the majority of primary tumors of the brain parenchyma in adults, and of these, glioblastoma is both the most common and most aggressive.
2. Mutations in isocitrate dehydrogenase 1 (*IDH1*) and 2 (*IDH2*) drive the growth of a subset of astrocytomas and oligodendrogliomas and is associated with a more positive prognosis compared to their IDH wild-type counterparts.
3. As of 2016, the World Health Organization classifies tumors of the central nervous system by *integrated diagnoses* that incorporate histology, grade, and molecular profiling.
4. Maximal safe resection, radiation therapy, and chemotherapy, specifically alkylating chemotherapy, are the mainstays of glioma management.

INTRODUCTION

Gliomas comprise a group of primary central nervous system (CNS) neuroepithelial tumors that arise from glial progenitor cells in the brain and spinal cord. Historically, gliomas were classified into different tumor types based solely on their histologic resemblance to glial cell lineages, including astrocytomas, oligodendrogliomas, ependymomas, and several uncommon types of gliomas and glioneuronal tumors. Recently, the World Health Organization (WHO) redefined gliomas into entities comprising characteristic histologic and molecular signatures, arriving at *integrative diagnoses*. Poorly defined histologic diagnoses, such as oligoastrocytomas, have been removed except for cases in which molecular characterization is not available.

Gliomas rarely metastasize outside of the CNS and are not staged like systemic malignancies. Instead, gliomas are graded based on histopathologic features that predict aggressiveness. Tumors with malignant features are often referred to as *high-grade gliomas*, in contrast to *low-grade gliomas* (LGGs), which in spite of their more benign histologic appearance, are often not clinically benign. The location and invasiveness of most LGGs that occur in adults often makes them difficult to completely resect, leading to recurrent disease, as well as significant morbidity and mortality. The lowest grade gliomas (such as pilocytic astrocytomas) are an exception and are often surgically curable, but they rarely occur in adults.

This chapter focuses on astrocytomas and oligodendrogliomas, the most common glioma subtypes in adults. Other glioma subtypes that are rare in adults but commonly encountered in children, including ependymoma and glioneuronal tumors, are described separately in Chapter 150 *Congenital Brain Tumors in Children*.

Epidemiology

Gliomas are relatively rare tumors with an estimated annual incidence of 4.67 to 5.73 per 100,000 persons but are the most common malignant primary brain tumors in adults. Glioblastoma, a WHO grade IV astrocytoma, is the most common, and unfortunately, the most aggressive of all gliomas. Despite their rarity, gliomas rank as some of the most devastating cancers in terms of years of life lost.

In general, the incidence of gliomas is higher in men than in women and in non-Hispanic whites compared to blacks, Hispanics, Asians, or Native Americans. High-grade gliomas are commonly diagnosed in the seventh and eighth decades of life, whereas LGGs peak in incidence in the fourth and fifth decades.

There are very few known risk factors for the development of gliomas. The only clear environmental risk factor is exposure to high-dose ionizing radiation to the brain or spinal cord (eg, prophylactic cranial irradiation in children and adolescents with leukemia), while there is a negative association with atopy. To date, an association between gliomas and nonionizing radiation, such as cellular phone use, has not been established. Several rare genetic tumor predisposition syndromes are associated with increased incidence of gliomas, including germline *NF1* or *NF2* mutation in neurofibromatosis types I and II, *TSC1* or *TSC2* mutation in tuberous sclerosis, mutations in the mismatch repair machinery in Lynch syndrome and *TP53* mutation in Li-Fraumeni syndrome, among others.

Pathobiology

Like patients with brain metastases, patients with gliomas present with diverse clinical symptoms and signs that are related to tumor location, size, and growth rate, rather than tumor type. One exception is a subset of LGGs including oligodendrogliomas and some glioneuronal tumors which are associated with a high incidence of epilepsy. Gliomas can arise in the supra- or infratentorial brain, spinal cord or less commonly, spread to the cerebrospinal fluid and leptomeninges. Extracranial metastases are rare but have been described. Focal symptoms such as hemiparesis, aphasia, ataxia, visual field deficits, or cranial neuropathies result from localized invasion or compression of critical brain structures, whereas generalized symptoms such as headache, vomiting, lethargy, and confusion tend to be the result of increased intracranial pressure from tumor mass, edema, or obstructive

hydrocephalus. Seizures resulting from an underlying glioma are invariably focal in origin but may rapidly generalize, making it difficult to recognize their partial onset. Although seizures or symptoms from intratumoral hemorrhage appear suddenly, most other symptoms produced by gliomas present over days to weeks. High-grade gliomas tend to present with more rapidly progressive focal or generalized symptoms, whereas LGGs frequently present with seizure without progressive neurologic deficits. Depending on location, even large tumors can produce surprisingly few symptoms, as in the case of LGGs, to which the brain can gradually adapt. Consequently, an apparently normal neurologic exam cannot rule out an underlying glioma, and a thorough history and physical exam must be coupled with a high degree of clinical suspicion in order to know when to consider the diagnosis and obtain neuroimaging.

Molecular Features of Gliomas

Recent studies have shed light on the mechanisms underlying gliomagenesis, that is, the formation and development of gliomas. Table 100.1 summarizes some of the most characterized genomic alterations associated with certain glioma subtypes. The presence of an isocitrate dehydrogenase (*IDH1* or *IDH2*) mutation is the single most important prognostic factor in astrocytomas and oligodendrogliomas, which are the most common gliomas in adults. This recognition has led to the stratification of these tumors by the presence or absence of an *IDH* mutation, defining new disease entities. Although not directly involved in tumor formation, *MGMT* promoter methylation has strong prognostic importance in glioma survival and response to therapy.

IDH1 and IDH2 Mutations

IDH1 and IDH2 are enzymes that catalyze the conversion of isocitrate to α-ketoglutarate in the cytoplasm and in the mitochondrion, respectively. Mutations in the *IDH1* or *IDH2*, can confer a neo-enzymatic function whereby α-ketoglutarate is converted to 2-hydroxyglutarate. This "oncometabolite" competitively inhibits α-ketoglutarate–dependent dioxygenases resulting in DNA hypermethylation, complex changes in gene expression, and ultimately tumorigenesis. Mutations in IDH are associated with both gliomas and some forms of leukemia and other solid tumors.

IDH mutation, most commonly a point mutation that substitutes a histidine for an arginine at amino acid position 132 (*IDH1 R132H*), is identified in the majority of low-grade astrocytomas and oligodendrogliomas but only about 5% of glioblastoma. Most IDH-mutant glioblastoma are "secondary" high-grade tumors, that is, they arise from precursor lower grade IDH-mutant astrocytomas. IDH-mutant gliomas have a significantly better prognosis than their IDH wild-type counterparts, and IDH mutation is a stronger prognostic determinant than histologic grade. Moreover, IDH mutation is potentially a clinically targetable alteration, and a number of clinical trials are currently exploring the efficacy of inhibitors of mutant IDH.

TABLE 100.1 Genomic Alterations Associated with Glioma Subtypes

Glioma Subtype	Genomic Alteration(s)	Identification
Dysembryoplastic neuroepithelial tumors (WHO grade I)	***BRAF-V600E*** mutation	Genetic sequencing IHC against BRAF-V600E mutant protein
Ganglioglioma (WHO grade I, rarely WHO grade III)	***BRAF-V600E*** mutation	Genetic sequencing IHC against BRAF-V600E mutant protein
Pilocytic astrocytoma (WHO grade II)	***BRAF*** fusions, incl. ***KIAA1549-BRAF*** ***BRAF*** mutations Other MAPK pathway mutations Germline **NF1** mutations	IHC for KIAA1549-BRAF fusion protein Genetic sequencing Clinical diagnosis of NF1
Pleomorphic xanthoastrocytoma (WHO grade II)	***BRAF*** mutations (incl. ***BRAF-V600E***)	Genetic sequencing
Subependymal giant cell astrocytoma (WHO grade I)	Germline or sporadic ***TSC1/TSC2*** mutations	Genetic sequencing Clinical or genetic diagnosis of tuberous sclerosis
IDH wild-type astrocytomas • Diffuse astrocytoma, IDH wild type (WHO grade II) • Anaplastic astrocytoma, IDH wild type (WHO grade III) • Glioblastoma, IDH wild type (WHO grade IV)	Gain of chromosome 7 (incl. **EGFR**) Loss of chromosome 9 (incl. **CDKN2A/B**) Loss of chromosome 10 (incl. **PTEN**) ***TERT*** promoter mutations No ***IDH*** mutation	FISH or CGH for chromosomal aberrations IHC for EGFR amplification Genetic sequencing
IDH-mutant astrocytomas • Diffuse astrocytoma, IDH-mutant (WHO grade II) • Anaplastic astrocytoma, IDH-mutant (WHO grade III) • Glioblastoma, IDH-mutant (WHO grade IV)	***IDH1*** or ***IDH2*** mutation ***ATRX*** mutation ***TP53*** mutation	IHC for canonical *IDH1-R132H* mutation or genetic sequencing for noncanonical mutations IHC for ATRX (loss of staining in mutation) IHC for p53 (increased staining in mutation) Genetic sequencing
Oligodendroglioma • Diffuse oligodendroglioma, IDH-mutant (WHO grade II) • Anaplastic oligodendroglioma, IDH-mutant (WHO grade III)	***IDH1*** or ***IDH2*** mutation Codeletion of chromosome arms 1p and 19q ***TERT*** promoter mutations	IHC for canonical *IDH1-R132H* mutation or genetic sequencing for noncanonical mutations FISH or CGH for 1p/19q codeletion
Diffuse midline glioma (WHO grade IV)	***H3K27M*** mutation	Genetic sequencing IHC for H3K27M mutant protein
Ependymoma (WHO grade II or III)	Multiple chromosomal aberrations ***RELA*** and ***YAP1*** gene fusions in a subset of ependymoma	Genetic sequencing FISH for RELA fusion

Abbreviations: ATRX, alpha-thalassemia X-linked mental retardation; CGH, comparative genomic hybridization; EGFR, epidermal growth factor receptor; FISH, fluorescence in situ histochemistry; IDH, isocitrate dehydrogenase; IHC, immunohistochemistry; incl., including; MAPK, mitogen-activated protein kinase; NF1, neurofibromatosis type 1; PTEN, phosphatase and tensin homolog; WHO, World Health Organization.

O^6-Methylguanine-DNA Methyltransferase Promoter Methylation

O^6-methylguanine-DNA methyltransferase (MGMT) is a DNA repair protein capable of repairing the DNA cross-linking created by alkylating agents and is associated with resistance to alkylating chemotherapy (eg, temozolomide, lomustine [CCNU]). In a subset of gliomas, the promoter for the *MGMT* gene is hypermethylated, such that the gene is epigenetically silenced, and MGMT is not expressed. High-grade glioma patients with tumors that have methylated *MGMT* promoters show significantly increased survival compared to patients with unmethylated *MGMT*. For example, in a pivotal trial by Stupp and colleagues of patients with glioblastoma treated with concurrent chemoradiation with temozolomide followed by adjuvant temozolomide versus radiation therapy (RT) alone, patients with methylated *MGMT* promoters showed an improvement in median survival from 15.3 to 23.4 months, whereas those with unmethylated *MGMT* had only minimal improvement from 11.8 to 12.6 months. Thus, *MGMT* promoter methylation is a potent prognostic factor in gliomas.

Approximately 40% of glioblastoma patients have methylated *MGMT* promoters, and *MGMT* promoter methylation status plays a prominent role in medical decision making, particularly as *MGMT* methylation status does not tend to change at recurrence. *IDH* mutation is also associated with *MGMT* promoter methylation, given the hypermethylation phenotype of IDH-mutant gliomas. However, the prognostic significance of *MGMT* promoter methylation has not been established in LGGs.

Diagnosis

Brain or spinal cord magnetic resonance imaging (MRI) with and without gadolinium contrast is the imaging modality of choice when a CNS tumor is suspected. MRI provides superior resolution and tissue characterization compared to computed tomography scanning and has become an integral part of tumor diagnosis, treatment planning, surveillance, and therapeutic monitoring. MRI sequences required for adequate tumor characterization include T2/fluid-attenuated inversion recovery (FLAIR) and T1 pre– and post–gadolinium contrast–enhanced images. High-resolution three-dimensional T1-weighted sequences allow improved visualization in multiple orientations and are often used in presurgical planning and subsequent monitoring. Additional useful imaging includes diffusion-weighted images with apparent diffusion coefficient maps to assess for hypercellularity as well as susceptibility-weighted images to identify the presence of blood products or calcification.

Gliomas generally appear as infiltrating, poorly defined white matter lesions that are hyperintense on T2/FLAIR and hypointense on T1-weighted images. They predominantly arise in the cerebral hemispheres, although brain stem and cerebellar lesions are common in children. Although there are exceptions, most LGGs in adults tend to be infiltrative and nonenhancing with mild to moderate mass effect, whereas high-grade gliomas are more often heterogeneously enhancing, frequently with regions of necrosis and marked surrounding T2/FLAIR hyperintense edema contributing significant mass effect. Gadolinium enhancement is the result of contrast extravasation from abnormal tumor vessels, and although the extent of enhancement does not always correlate with degree of malignancy, the development of new contrast enhancement can signal transformation to higher grade. It is important to remember that the area of enhancement does not define the extent of the tumor, particularly in diffuse gliomas. Because of their abnormal vasculature, various tumor types, including high-grade gliomas, can present with hemorrhage. For this reason, it is important to obtain delayed follow-up imaging in any patient presenting with an unexplained intracerebral hemorrhage to rule out an underlying tumor. Similarly, although restricted diffusion on MRI is often equated with infarction or abscess, hypercellular tumors like gliomas can similarly restrict diffusion of water. This finding can lead to some confusion about the diagnosis in patients presenting with acute symptoms, although gliomas tend to spare cortical gray matter and do not remain confined to a single vascular territory.

In recent years, advanced imaging techniques have been developed to improve diagnostic capability and surgical planning for glioma patients. Many of these techniques aim to move beyond anatomic characterization in order to gain greater insights into tumor biology. Some of the techniques being studied for their use in glioma include magnetic resonance (MR) diffusion tensor imaging, MR perfusion, MR spectroscopy including for 2-hydroxyglutarate, and positron emission tomography/computed tomography.

The diagnosis of a glioma is ultimately made by tissue sampling. Traditionally, morphologic similarity to normal glial cells is used to assign tumors to particular glioma subtypes, including astrocytoma, oligodendroglioma, ependymoma, and glioneuronal tumors. Within each of these tumor types, the presence or absence of specific histologic features is used to infer tumor behavior and growth rate and to assign tumors to pathologic grades, with implications for prognosis and treatment. Some of the features that determine tumor grade include cellular atypia, anaplasia, mitotic activity, endothelial proliferation, and necrosis. Gliomas are graded using the WHO classification system that includes grades I to IV. WHO grades I and II are considered low-grade tumors, whereas WHO grades III and IV are considered high-grade, malignant tumors. Based on their pathologic appearance, LGGs have occasionally been referred to as *benign*; however, this term is a misnomer because the clinical course of LGGs in adults almost always includes recurrence and progression to higher grade malignancy and death.

Advances in our understanding of the molecular features defining brain tumors and their prognosis led to a revision of the *WHO Classification of Tumours of the Central Nervous System* in 2016. Rather than diagnoses based purely on histology, primary brain tumors are now largely classified by *integrated diagnoses*, which incorporate histology, grade, and molecular alterations that might better predict prognosis and response to therapy. Perhaps most importantly for adult neurooncology, astrocytomas and oligodendrogliomas are now defined by their IDH mutational status as well as other accompanying mutations (discussed in detail in the sections in the following text). For high-grade gliomas, MGMT promoter methylation status is also incorporated into the integrated diagnosis.

Management

There are a number of challenges that clinicians face in the treatment of gliomas, including their infiltrative nature, often poor response to RT and chemotherapy and the impact of treatment on healthy brain tissue. General management considerations are presented in this section, whereas recommendations based on specific diagnoses are discussed in the sections that follow.

Surgery

Surgery serves both a diagnostic and therapeutic purpose in glioma management. Although stereotactic biopsy can establish a diagnosis, usually, craniotomy and open tumor resection are preferred to avoid a misdiagnosis from undersampling the lesion and for therapeutic benefit. Unfortunately, even when all radiographically visible tumor is excised, viable microscopic glioma cells generally remain and eventually regrow. Therefore, except in cases of certain WHO grade I gliomas where gross total resection can be curative, surgery alone is not definitive therapy in the management of gliomas.

Extent of resection is an important prognostic factor in gliomas and impacts overall survival. The exact extent of resection that confers a survival benefit or how much more is gained with increasing resection (ie, 80% vs 90% resection) is unknown and likely depends on the histology and molecular factors such as IDH mutational and MGMT promoter methylation status. Prior experience does show that overly aggressive resection at the expense of neurologic function can have a detrimental effect on survival and certainly on functional status. For this reason, the goal of most glioma surgery is *maximal safe resection* of the lesion, which may be guided by functional imaging such as functional MRI, intraoperative functional mapping and intraoperative imaging, as well as the use of 5-aminolevulinic acid to identify residual tumor under fluorescent light. Extent of resection in high-grade gliomas should be measured by a postoperative MRI within 48 hours of the procedure, when it is easiest to discern residual tumor from postoperative blood products.

Radiation Therapy

RT induces DNA strand breaks either directly (in the case of particle therapy) or indirectly through the production of reactive oxygen free radicals (in the case of photon therapy). Cells undergoing mitosis are more sensitive to the damaging effects of RT, and cancer cells are targeted by virtue of their rapid division and impaired DNA repair mechanisms. RT is generally delivered in repeated doses known as *fractions* in order to allow normal cells to repair sublethal damage. Most RT for glioma involves fractionated external beam photon therapy generated by linear accelerators that is delivered from multiple angles toward the tumor location. Dose varies depending on the tumor type, but fractions of 1.8 to 2 Gy are typically delivered to a total dose of 40 to 60 Gy. RT planning involves targeting the T2/FLAIR-defined glioma volume plus a 1.5- to 2-cm margin for subclinical infiltrative disease and a small volume for uncertainties in planning or treatment delivery.

A number of RT techniques improve the ability to more precisely target tumor while sparing normal surrounding brain tissue with the intent of minimizing toxicity. Intensity-modulated radiation therapy, together with three-dimensional conformal planning, allows for delivery of RT that better conforms to the contours of the intended treatment area. Single-fraction stereotactic radiosurgery or stereotactic radiotherapy, given in one or a few fractions, involves the use of focused radiation beams to deliver very high doses of radiation to a small, well-defined area while delivering minimal dose to surrounding structures. Because of its small well-defined target volume, stereotactic radiosurgery/stereotactic radiotherapy is not ideal for most infiltrating gliomas and is not used routinely for initial radiotherapy, although it is occasionally used for focal recurrences. Proton beam RT is a particle-based therapy whose advantage is the delivery of ionizing radiation at a defined target depth while sparing tissue both superficial and deep to the target. Because of limited availability, high cost, and long wait times, proton therapy is generally reserved for pediatric patients with low-grade tumors who are likely to benefit most from decreased risk of long-term side effects following RT to a developing brain. In spite of high-dose focal RT, most gliomas eventually recur at the original site of treatment.

The main adverse effects of RT include fatigue, headache, and focal neurologic deficits related to the irradiation of healthy brain, particularly inattention and memory impairment, and these may be immediately evident after treatment or delayed. RT can result in capillary permeability and brain necrosis that can mimic the radiographic appearance of high-grade glioma and may be symptomatic, a phenomenon termed *pseudoprogression*, *treatment-related changes*, or *radiation necrosis*. Higher doses of RT, reirradiation, concurrent chemotherapy and possibly MGMT promoter methylation increase the risk of pseudoprogression.

Chemotherapy

Systemic therapies aim to target viable cancer cells that extend beyond the margins of surgical resection and irradiation and/or to enhance the effect of RT. Numerous chemotherapeutic agents have been used in the treatment of both LGGs and high-grade gliomas, including alkylating agents, antimetabolites, and topoisomerase inhibitors (Table 100.2). Most traditional chemotherapeutics work by inducing DNA damage or blocking DNA replication, with the greatest effect seen in rapidly dividing cells. Unfortunately, very few drugs have been proven to be effective in the treatment of gliomas. Alkylating agents such as the nitrosoureas and temozolomide have been the most successful agents in the treatment of glioma and remain a mainstay of current therapy.

More recently, multiple molecularly targeted agents and immunotherapy have been developed in an attempt to inhibit glioma growth. The only U.S. Food and Drug Administration (FDA)-approved targeted therapies for gliomas are everolimus for subependymal giant cell astrocytomas in patients with tuberous sclerosis and bevacizumab, a humanized monoclonal antibody that binds vascular endothelial growth factor (VEGF) preventing activation of VEGF receptors, one of the major signals used by tumors to recruit new blood vessels. Bevacizumab has been particularly useful as palliative chemotherapy in glioblastoma, given a potent normalizing effect on the tumor vasculature that improves symptom burden by inhibiting cerebral edema. Unfortunately, numerous phase III studies have failed to show a survival benefit of treatment with bevacizumab in glioblastoma. Recently, the FDA-approved pembrolizumab, an immune checkpoint inhibitor for solid tumors with high microsatellite instability and larotrectinib, a small molecule inhibitor of tropomyosin receptor kinase proteins, for neurotrophic receptor kinase 1 (NTRK) fusion proteins in a tissue-agnostic fashion. However, these represent only a very small proportion of gliomas.

Outcome

The prognosis for patients with glioma varies substantially based on the specific diagnosis. As a general rule, these tumors are incurable despite aggressive multimodality therapy, recur, and are associated with significant morbidity and mortality. WHO grade I gliomas are the exception, as gross total resection can be curative. In high-grade gliomas, age, functional status, extent of resection, IDH mutational status, and MGMT promoter methylation

TABLE 100.2 Overview of Chemotherapeutic Agents Frequently Used in the Treatment of Glioma

Drug	Indication	Dose Regimen	Side Effects	Monitoring
Temozolomide	GBM Anaplastic astrocytoma/ oligodendroglioma Low-grade glioma	Chemoradiation: 75 mg/m²/d orally daily for 6 wk Adjuvant: 150-200 mg/m²/d for 5 d every 28 d	Nausea, vomiting Fatigue Myelosuppression—especially lymphopenia, thrombocytopenia	CBC with differential weekly during chemoradiation, days 21 and 28 during adjuvant dosing, or more frequently
Lomustine/CCNU (alone or in combination as PCV)	GBM (recurrent) Anaplastic astrocytoma/ oligodendroglioma Low-grade glioma	100-130 mg/m² orally as single dose every 6 wk	Nausea, vomiting Myelosuppression—especially lymphopenia, thrombocytopenia Pulmonary fibrosis	CBC with differential weekly × 6 wk Hepatic and renal function Pulmonary function at baseline and periodically thereafter
Carmustine/BCNU	GBM (recurrent)	150-200 mg/m² IV as single dose every 6 wk	Nausea, vomiting Myelosuppression Pulmonary fibrosis Headache Rare infusion reaction	
Carmustine wafers	GBM	Up to eight wafers (61.6 mg) implanted in the surgical bed at time of resection	CNS edema/local inflammation Infection CSF leak Seizures	Clinical monitoring for seizure/CNS infection/ edema
Procarbazine (PCV)	Low-grade glioma Anaplastic Oligodendroglioma	60-75 mg/m² orally days 8-21 every 6 wk	Nausea, vomiting Myelosuppression Encephalopathy	CBC with differential Hepatic and renal function tests
Vincristine (PCV)	Low-grade glioma Anaplastic Oligodendroglioma	1.4 mg/m² IV days 8 and 29 every 6 wk	Sensorimotor peripheral neuropathy Seizures	CBC with differential, electrolytes, hepatic function, uric acid levels
Bevacizumab	GBM (recurrent)	10 mg/kg IV every 2 wk	Hemorrhage Thrombosis Impaired wound healing HTN Proteinuria RPLS	CBC with differential, blood pressure, urine protein

Abbreviations: CBC, complete blood count; CNS, central nervous system; CSF, cerebrospinal fluid; GBM, glioblastoma; HTN, hypertension; IV, intravenous; PCV, procarbazine, lomustine, and vincristine; IV, intravenous, RPLS, reversible posterior leukoencephalopathy syndrome.

dictate prognosis. In IDH-mutant gliomas, the majority of which are low-grade tumors, tumors with 1p/19q codeletion (ie, oligodendrogliomas) have a more favorable prognosis compared to noncodeleted tumors (ie, astrocytomas).

In the following sections, we review the most common gliomas with respect to their presentation, management, and prognosis.

ASTROCYTOMAS

Pilocytic Astrocytoma

Introduction

Pilocytic astrocytomas are relatively well-circumscribed WHO grade I tumors that primarily occur in children and young adults. Molecularly, they are characterized by mutations in the mitogen-activated protein kinase (MAPK) pathway. The mainstay of management is surgical resection, which can be curative in a large number of cases.

Epidemiology

Pilocytic astrocytomas make up about 5% of all gliomas and are the most common glioma in children, accounting for 15.3% of brain tumors in those younger than 19 years of age. Their incidence decreases with age, and they only rarely occur in older adults. Pilocytic astrocytomas are associated with neurofibromatosis type I, where they are estimated to occur in 15% to 20% of patients.

Pathobiology

Most pilocytic astrocytomas harbor alterations in the MAPK signaling pathway. The most common alteration involves duplication of a region of chromosome 7q34 to form a constitutively-active *BRAF* fusion protein, *KIAA1549-BRAF*. This mutation is most commonly associated with cerebellar pilocytic astrocytomas. Other mutations associated with these tumors include other *BRAF* fusion products, point mutations in *BRAF* such as *BRAF-V600E*, *NTRK* gene fusions and mutations in *FGFR1*. There is a strong association between *NF1* mutation and pilocytic astrocytomas in neurofibromatosis type I, specifically as optic pathway gliomas. Identification of an IDH mutation in a presumed pilocytic astrocytoma should raise suspicion for an alternative diagnosis.

Pilocytic astrocytomas can occur anywhere in the neuraxis, although they most frequently arise in the cerebellum. They also have a predilection for the anterior optic pathway, particularly in NF1, where they display an even more indolent course than sporadic tumors. In fact, optic pathway pilocytic astrocytomas are so characteristic of NF1 that any child diagnosed with this tumor should be evaluated for NF1. Pilocytic astrocytomas present insidiously with symptoms related to their location. Infratentorial tumors often present with progressive headache, nausea, and vomiting related to hydrocephalus, whereas optic pathway tumors present with progressive visual loss or proptosis. Seizures are an uncommon presentation because these tumors rarely involve the cerebral cortex.

FIGURE 100.1 Pilocytic astrocytoma. Hematoxylin and eosin–stained section of histologic specimen highlighting the bipolar cells and thin processes of pilocytic astrocytomas. The *black arrow* denotes a Rosenthal fiber. The *yellow arrowhead* denotes a single mitosis. (Photos courtesy of Derek H. Oakley.)

Diagnosis

On MRI, pilocytic astrocytomas appear well-circumscribed with bright contrast enhancement and frequent cyst formation. Diagnosis requires biopsy or resection for tissue sampling. Histologically, there is a biphasic pattern of growth with areas of bipolar cells with Rosenthal fibers and loose-textured multipolar cells with microcysts (Fig. 100.1). Despite the radiographic appearance of a defined border, pilocytic astrocytomas do not have a true capsule, and although they are considered noninvasive, they often microscopically infiltrate surrounding brain parenchyma. As detailed in the previous section, molecular testing of the tumor can confirm the diagnosis of pilocytic astrocytoma, especially if it uncovers a *BRAF* fusion.

Management

Gross total resection of pilocytic astrocytomas can be curative and should be the primary treatment consideration whenever possible. Even partial resection can lead to long-term survival, with up to 87% and 82% of patients surviving at 10 and 20 years. Regardless of the extent of resection, patients must be followed long-term to monitor for infrequent progression. Because of their indolent natural history, even partially resected pilocytic astrocytomas can be subsequently monitored without adjuvant therapy until there is evidence of further growth. Documented cases of spontaneous remission following partial resection appear to validate this wait-and-see approach. RT or chemotherapy (temozolomide, bevacizumab, and irinotecan have been used) can be considered in cases with inoperable or progressive tumors, although the long-term benefits of these modalities are uncertain.

Outcome

The prognosis from pilocytic astrocytoma depends on resectability, as those that cannot be completely resected tend to recur. However, data from the 2011-2015 Central Brain Tumor Registry of the United States demonstrates 10-year survival rate of 92.2% for all documented cases, suggesting an overall positive prognosis. Malignant transformation only occurs in a minority of cases, although there is unfortunately no way to predict which tumors will transform.

Diffuse Astrocytoma

Introduction

Diffuse astrocytomas are WHO grade II infiltrative astrocytic tumors that typically affect otherwise healthy young adults. As is the case with high-grade astrocytomas, the presence of an IDH mutation defines a disease category with a better prognosis compared to IDH wild-type astrocytomas. Management involves maximal safe resection, RT, and chemotherapy, although the timing of these can be influenced by multiple factors including symptom burden, rate of growth, and presence of an IDH mutation. Although termed *low-grade gliomas*, the recurrence rate of these tumors and their potential for malignant transformation are high.

Epidemiology

Diffuse astrocytomas make up 7% of all gliomas with an annual incidence of 0.46 per 100,000 and a peak incidence in the fourth decade of life. There is a slight male predominance.

Pathobiology

The mechanism by which diffuse astrocytomas develop from astrocyte precursor cells remains poorly understood. Mutations in *IDH1* or *IDH2* are found in 68% to 90% of all diffuse astrocytomas and are likely drivers of gliomagenesis in these tumors. As opposed to their oligodendroglial counterparts, IDH-mutant diffuse astrocytomas tend to harbor loss of function mutations in *ATRX* and *TP53*. IDH wild-type diffuse astrocytomas are rare and likely represent a heterogeneous group of astrocytomas. In a recent update to their *Classification of Tumours of the Central Nervous System*, the WHO has advocated for the designation of "diffuse astrocytic glioma, IDH wild type with molecular features of glioblastoma, WHO grade IV" for IDH-wild type diffuse astrocytomas with TERT promoter mutation, epidermal growth factor receptor (EGFR) amplification, or combined whole chromosome 7 gain and chromosome 10 loss given their more aggressive clinical course.

Diffuse astrocytomas can occur anywhere in the CNS, although they preferentially arise in the cerebral hemispheres in adults. They frequently present with seizures but depending on the location and size can also cause focal symptoms or cognitive and behavioral change.

Diagnosis

Diffuse astrocytomas generally appear as ill-defined homogeneous regions of T1 hypointense signal and T2/FLAIR hyperintensity, although they tend to infiltrate beyond the T2/FLAIR margins visible on MRI. Diffuse astrocytomas generally have minimal contrast enhancement, and the development of new contrast enhancement can signal progression to higher grade (Fig. 100.2).

Definitive diagnosis requires biopsy or resection for tissue sampling. Histologically, diffuse astrocytomas appear as hypercellular tissue with cells resembling well-differentiated astrocytes and occasionally demonstrate nuclear atypia but only rare mitotic activity (Fig. 100.3, panel A). Markers of cellular proliferation such as Ki-67 or MIB E3 ubiquitin protein ligase 1 (MIB-1) typically show a growing fraction of less than 4%. By definition, diffuse astrocytomas have no necrosis or endovascular proliferation.

FIGURE 100.2 World Health Organization (WHO) grade II diffuse astrocytoma with progression to WHO grade III anaplastic astrocytoma. Initial T2-weighted fluid-attenuated inversion recovery (FLAIR) (A) and gadolinium contrast–enhanced T1-weighted (B) magnetic resonance imaging sequences of a patient with diffuse astrocytoma that despite radiation therapy recurred with more extensive T2/FLAIR signal (C) and new patchy enhancement (D) that was proven by biopsy to represent transformation to WHO grade III anaplastic astrocytoma.

FIGURE 100.3 Astrocytomas. **A:** Hematoxylin and eosin (H&E)-stained section of a World Health Organization (WHO) grade II diffuse astrocytoma showing hypercellular brain tissue infiltrated by cells with elongated nuclei *(yellow arrowhead)*. **B:** WHO grade IV glioblastoma on H&E-stained section with high hypercellularity and marked atypia. *Asterisk* denotes necrosis with pseudopalisading architecture. *Yellow arrowhead* highlights an abnormal capillary with two stacked endothelial cell nuclei characteristic of microvascular proliferation. (Photos courtesy of Derek H. Oakley.)

Diffuse astrocytomas should stain positive for glial fibrillary acidic protein (GFAP).

IDH mutation is typically identified by immunohistochemistry against mutant *IDH1 R132H* or genetic sequencing to look for noncanonical *IDH1* or *IDH2* mutations. In IDH-mutant diffuse astrocytomas, *ATRX* mutation leads to loss of ATRX staining on immunohistochemistry, whereas *TP53* mutation leads to strong nuclear staining. As above, IDH wild-type diffuse astrocytomas typically harbor molecular signatures more suggestive of glioblastoma on genetic sequencing.

Management

The approach to diffuse astrocytoma is complex, and a number of questions remain regarding various aspects of treatment. Management incorporating observation, surgery, RT, and chemotherapy is individualized based on tumor location, molecular profile, and patient characteristics.

Available evidence increasingly supports surgical resection over observation and retrospective studies suggest a survival benefit from more extensive resection. Early surgery is generally recommended for patients with large symptomatic tumors, although the management of patients with small incidentally found or minimally symptomatic tumors is less clear. It is possible that early resection in this patient population confers a survival benefit as well, but in the absence of reliable evidence, monitoring for clinical or radiographic progression is also an option. It is current practice to attempt a maximal safe resection by an experienced brain tumor neurosurgeon in patients undergoing surgery, although the diffuse nature of this disease may in some cases limit surgical options to a biopsy to establish a diagnosis.

Approved adjuvant therapies include RT and chemotherapy, although the optimal timing and dosing of these remains unclear. One seminal study showed that postoperative RT delayed the time to progression but did not prolong overall survival LEVEL 1.[1] In light of the potential long-term neurocognitive effects of RT, these results have been used to justify delaying RT, although tumor progression may also negatively impact cognitive function. Retrospective studies have helped define a population of "high-risk" LGG patients, which may benefit from immediate postoperative therapy, including age older than 40 years, large preoperative tumor size, subtotal resection, high tumor proliferation rate by immunohistochemistry (MIB-1 >3%) and absence of an IDH mutation. IDH-mutant diffuse astrocytomas are at relatively higher risk for tumor progression compared to IDH-mutant diffuse oligodendrogliomas, which are characterized by loss of chromosome arms 1p and 19q in addition to IDH mutation.

Immediate or delayed postoperative RT is advised for all patients with diffuse astrocytomas receiving adjuvant treatment. Two studies addressing RT dose found that lower doses of RT (either 45 or 50.4 Gy) were equivalent to higher dose (59.4 or 64.8 Gy) LEVEL 1.[2,3] As a result, most patients currently receive 50 to 54 Gy.

The role of chemotherapy in diffuse astrocytomas is recently being defined. The Radiation Therapy Oncology Group (RTOG) 9802 study, which did not make a distinction between diffuse astrocytomas and diffuse oligodendrogliomas, found a significant benefit on median survival to adjuvant RT followed by chemotherapy with procarbazine, cyclophosphamide, vincristine (PCV) compared to RT alone in patients with high-risk LGGs (13.3 vs 7.8 y, respectively) LEVEL 2.[4] It is currently common practice to use either sequential RT followed by adjuvant PCV or temozolomide, or concurrent chemoradiation with temozolomide followed by adjuvant temozolomide for patients with diffuse astrocytoma after surgical resection. Close monitoring with contrast-enhanced MRI brain is advised for all patients with diffuse astrocytoma.

Outcome

Despite aggressive treatment, most diffuse astrocytomas will recur or undergo malignant transformation. Prognosis depends on age, functional status, neurologic deficits, tumor size and degree of resection, presence of enhancement on MRI brain, and molecular features including IDH mutation, which is a strong positive prognostic factor. The 5-year survival for adults with diffuse astrocytoma is 72.2% for those 15 to 39 years of age and 31.2% for those older than 40 years old according to Central Brain Tumor Registry of the United States 2011-2015 data. It should be noted, however, that these data predate the stratification of diffuse astrocytomas by IDH mutation as well as recent changes in standard of care such as the incorporation of early chemotherapy.

Anaplastic Astrocytoma and Glioblastoma

Introduction

WHO grade III anaplastic astrocytoma and WHO grade IV glioblastoma make up the high-grade astrocytomas. These are aggressive tumors that tend to progress quickly despite multimodality therapy. A subset of these harbor mutations in *IDH* and have evolved from precursor IDH-mutant diffuse astrocytomas. Methylation of the *MGMT* promoter is associated with an improved prognosis and response to therapy. Management includes maximal safe resection, concurrent chemoradiation followed by adjuvant chemotherapy, and tumor-treating fields. However, they are associated with significant morbidity and severely shortened lifespan in virtually all cases.

Epidemiology

Glioblastoma is the most common primary malignant brain tumor, making up 14.7% of all primary brain tumors and 56.6% of all gliomas. The annual incidence of glioblastoma is 3.21 per 100,000 and has a median age at diagnosis of 65 years. Anaplastic astrocytomas make up just 6.7% of all gliomas and have an annual incidence of 0.41 per 100,000. Both are much less frequent in children than in adults and have a male predominance.

Pathobiology

As for diffuse astrocytomas, the development of anaplastic astrocytomas and glioblastoma from glial precursor cells is not completely understood. Secondary glioblastoma, which arise from malignant transformation of low-grade diffuse astrocytomas are strongly associated with IDH mutation (85%-88%), as are anaplastic astrocytomas (73%). On the other hand, the majority of primary glioblastoma (ie, those not arising in patients with prior diagnosis of low-grade astrocytoma) are IDH wild type, with only 5% harboring IDH mutations. Whereas IDH mutation is the likely driver of gliomagenesis in IDH-mutant tumors, no single mutation is associated with the evolution of IDH wild-type astrocytomas. Rather, recent studies in IDH wild-type glioblastoma suggest that the earliest genetic events involve large chromosomal gains or losses, particularly gains of chromosome 7 and loss of chromosome 9 or 10, leading to alterations in *EGFR*, *CDKN2A/B*, and *PTEN*, respectively.

Anaplastic astrocytomas and glioblastoma preferentially arise in the white matter of the cerebral hemispheres. Symptoms result from tumor location and mass effect and can include focal neurologic deficits, seizures, and headaches. Seizures are more common in anaplastic gliomas than glioblastoma.

Diagnosis

On MRI brain, high-grade astrocytomas usually appear as heterogeneously contrast-enhancing mass lesions surrounded by T2/FLAIR hyperintense signal with poorly defined margins that represent a combination of cerebral edema and nonenhancing tumor (Fig. 100.4). Diagnosis is made through tissue sampling. Histologically, both anaplastic astrocytomas and glioblastoma appear as hypercellular infiltrating astrocytic tumors with significant atypia and anaplasia as well as frequent mitoses suggestive of a high proliferation rate (Fig. 100.3, panel B). Glioblastoma additionally has evidence of necrosis, which may take on a pseudopalisading appearance, and/or microvascular proliferation. The diagnosis of an IDH mutation can be made by immunohistochemistry against mutant *IDH1 R132H*, or by genetic sequencing to look for noncanonical mutations in *IDH1 or IDH2*.

IDH-mutant anaplastic astrocytomas and glioblastoma typically display mutations in *ATRX* and *TP53* that may be evident on immunohistochemistry as *ATRX* loss and strong nuclear *TP53* staining. High-grade gliomas, especially IDH wild-type tumors, are very heterogeneous and genetic sequencing frequently reveals alterations in a number of pathways related to cancer, including *TERT* promoter mutations and mutations in receptor kinase signaling (eg, EGFR signaling), phosphoinositide 3-kinase/protein kinase B/mammalian target of rapamycin, retinoblastoma and MAPK pathways. *MGMT* promoter methylation is an important prognostic factor in glioblastoma and should be routinely tested in these patients.

Management

The overall approach to the treatment of high-grade gliomas involves maximal safe resection, concurrent chemoradiation followed by adjuvant chemotherapy, and tumor-treating fields

FIGURE 100.4 Glioblastoma. **A:** Gadolinium contrast–enhanced T1-weighted magnetic resonance imaging (MRI) scans of a patient who initially presented with headaches and had unremarkable imaging. **B:** The patient developed facial weakness that led to a repeat MRI just 3 months later that revealed a centrally necrotic peripherally enhancing mass. Gross total resection led to the diagnosis of glioblastoma **(C)**, but despite chemoradiation, within 6 months, the patient's tumor recurred **(D)** and infiltrated the contralateral hemisphere **(E)**.

(for glioblastomas). However, survival remains very poor, and experts advocate for the consideration of clinical trial enrollment for all patients with high-grade gliomas who are trial candidates.

Surgery

Maximal safe resection of the contrast-enhancing tumor by an experienced brain tumor neurosurgeon is recommended for all patients with anaplastic astrocytoma and glioblastoma. Extent of resection correlates with overall survival, although the exact amount of tumor resection that confers a survival advantage remains poorly defined. A recent meta-analysis of 37 studies evaluating extent of resection and overall or progression-free survival confirmed a survival advantage for patients with glioblastoma treated with gross total resection compared to subtotal resection, subtotal resection compared to biopsy, and any resection compared to biopsy, although the quality of the data was moderate to low. Overall, the literature suggests that resection of 70% to 80% of the enhancing tumor is sufficient to confer a survival advantage. Tumor resection is also preferred over biopsy because it enhances diagnostic accuracy and provides tissue for molecular testing that is important for prognostication and some treatment decisions.

Radiation Therapy

RT plays a central role in the treatment of patients with high-grade astrocytoma and is important for treating both gross and microscopic infiltrative disease that cannot be resected. Postoperative RT prolongs overall survival on average from 3 to 4 months to 7 to 12 months in glioblastoma and should be considered in all patients with WHO grade III and IV astrocytomas. Typically, it consists of involved field external beam RT delivered 5 days per week in fractions of 2 Gy to a total dose of 60 Gy. Importantly, in up to 40% of patients receiving initial treatment with RT with or without chemotherapy, early imaging can demonstrate increased enhancement and edema. Although these findings appear consistent with early tumor progression, in up to half of patients, the changes are actually the result of increased vessel permeability secondary to treatment, a phenomenon known as *pseudoprogression*. Patients with a methylated MGMT promoter may be at higher risk for pseudoprogression. A role for MR spectroscopy, MR perfusion, and positron emission tomography is being explored to better diagnose malignant glioma and to distinguish tumor progression from treatment-related pseudoprogression.

Chemotherapy

Chemotherapy plays an important role in the management of patients with high-grade astrocytomas. Interim results of the CATNON trial of non-1p/19q codeleted anaplastic gliomas (ie, anaplastic astrocytomas) suggest that treatment with RT and adjuvant temozolomide provides a survival benefit over RT alone in WHO grade III anaplastic astrocytoma (5-year survival of 55.9% vs 44.1%, respectively) LEVEL 1.[5] The study is also designed to answer the question of whether concurrent administration of daily temozolomide during RT followed by adjuvant temozolomide is superior to sequential RT followed by adjuvant temozolomide, but these results are not yet available. Although those data are pending for anaplastic astrocytoma, a landmark 2005 randomized phase III study comparing RT alone to RT plus concurrent and adjuvant temozolomide in patients with glioblastoma, firmly established the role of concurrent chemoradiation and adjuvant chemotherapy in glioblastoma LEVEL 1.[6,7] The addition of temozolomide prolonged median survival from 12.1 to 14.6 months and led to significantly higher 2- (26.5% vs 10.4%) and 5-year survival rates (10% vs 2%). A post hoc analysis of the results on the basis of *MGMT* methylation status tried to determine which patients benefited the most from the addition. The study found that patients whose tumors had a methylated *MGMT* promoter (ie, silenced MGMT) derived a greater benefit from temozolomide (21.7-month median survival and 46% 2-year survival) compared with patients without promoter methylation (12.7-month median survival, 13.8% 2-year survival) LEVEL 1.[8] In the current standard of care, temozolomide, an oral DNA alkylating agent with good brain penetration, is administered concurrently with RT followed by at least six monthly adjuvant cycles for patients with high-grade gliomas LEVEL 1.[6,7]

Recent evidence has suggested a role for more aggressive chemotherapy as initial treatment of glioblastoma with a methylated *MGMT* promoter. In 2019, Herrlinger and colleagues reported on a randomized, open-label, phase III trial of concurrent chemoradiation and adjuvant chemotherapy with CCNU plus temozolomide compared to temozolomide alone in patients with glioblastoma and *MGMT* promoter methylation suggested an improvement in overall survival from 31.4 to 48.1 months. The combination chemotherapy group has significantly more grade 3 or higher adverse events compared to the temozolomide arm. The study recruited a relatively small number of patients for a phase III study (n = 129), so the authors advise cautious interpretation of the results, and the practice has not yet become standard of care.

Another chemotherapeutic approach to the treatment of high-grade astrocytomas involves the use of biodegradable polymers containing the alkylating agent carmustine, also known as *BCNU*. These wafers, which can be implanted into a tumor bed immediately after resection, gradually release carmustine into the tissue surrounding the resection cavity in order to kill residual tumor cells. A phase III trial for newly diagnosed glioblastoma suggested a modest survival benefit from wafer implantation at the time of resection, with median survival increasing from 11.6 to 13.9 months, which led to FDA approval for the initial treatment of high-grade glioma LEVEL 3.[9] However, the up-front use of carmustine wafers has not been compared with oral temozolomide chemotherapy, so data are lacking to indicate whether there is a survival advantage over the current standard of care. Carmustine wafers are associated with significant toxicity including increased brain edema, infection, and seizures, and they can confound MRI interpretability. There are no trials assessing the safety or efficacy of adding carmustine wafers to standard chemoradiation. The uncertainty regarding the risks and benefits of carmustine wafers in conjunction with standard chemoradiation has limited the adoption of this approach in the initial treatment of high-grade glioma, and they have fallen out of favor in recent years.

Tumor Treating Fields

Tumor-treating fields are a relatively new addition to the standard of care for glioblastoma, having been approved by the FDA in 2011 for recurrent glioblastoma and 2015 for newly diagnosed glioblastoma LEVEL 1.[10-12] For this therapy, electrodes adhered to the scalp provide alternating electric fields with the goal of disrupting the mitotic spindle of rapidly proliferating cells. A phase III open-label clinical trial randomized newly diagnosed glioblastoma patients to standard of care concurrent

chemoradiation followed by adjuvant temozolomide along with the Novo-TTF-100A device or adjuvant temozolomide alone and revealed improved overall survival of 20.9 months in the tumor-treating fields group compared to 16.0 months in the control arm. The current iteration of the device requires a shaved head for electrode placement and has a small battery unit that must accompany the patient during use. It is advised that the device be worn for at least 18 hours a day.

Recurrent Astrocytoma

Most patients with high-grade astrocytomas will recur months to a few years after initial treatment. Repeat surgical resection may be considered for localized recurrences, particularly in cases where there is uncertainty in whether new contrast enhancement represents true recurrence or treatment-related changes (ie, pseudoprogression). However, surgery alone is usually not sufficient to alter the course of the disease. A randomized phase III trial suggests that carmustine wafers may modestly improve survival compared with placebo (31 vs 23 weeks) LEVEL 1.[13] Re-irradiation remains an option as well, particularly in cases of distant recurrences outside of the initial radiation field or recurrences years after initial irradiation. Tumor-treating fields are also FDA approved for recurrent glioblastoma, based on randomized open-label trial of tumor-treating fields versus physician's choice chemotherapy demonstrating comparable rates of survival in the two groups.

Systemic chemotherapeutic options for recurrence are limited and of limited efficacy. In patients with adequate performance status, participation in clinical trials should be seriously considered. In patients who are not clinical trial candidates, a number of salvage chemotherapy options exist. Rechallenge with temozolomide or other alkylating agents such as nitrosoureas (eg, lomustine, also known as *CCNU*) may be of benefit, particularly if the patient responded well to initial chemotherapy and in cases of tumors with methylated *MGMT* promoters. The antiangiogenic agent bevacizumab is also approved for treatment of recurrent glioblastoma and may be administered alone or in combination with cytotoxic chemotherapy. Bevacizumab is a humanized monoclonal antibody directed against VEGF, a key mediator of vascular permeability and angiogenesis. In high-grade glioma, bevacizumab often results in normalization of tumor blood vessels and a rapid decrease in enhancement, peritumoral edema, and mass effect. A phase II study of bevacizumab with or without concurrent irinotecan in glioblastoma demonstrated radiographic responses, which led to accelerated FDA approval of bevacizumab for recurrent glioblastoma. However, one phase III study of lomustine plus bevacizumab compared to lomustine alone in recurrent glioblastoma and two phase III trials of bevacizumab in combination with temozolomide and RT in newly diagnosed disease failed to show an overall survival benefit to the addition of bevacizumab LEVEL 1.[14-16] At this time, bevacizumab appears to be most beneficial as palliative chemotherapy for patients with significant symptoms who could benefit from tumor shrinkage or decreased peritumoral edema, either at the time of initial treatment or at recurrence.

Outcome

The median survival for patients with anaplastic astrocytoma is approximately 3 years, whereas patients with glioblastoma have a median survival of around 15 months. Of course, prognosis varies significantly between individuals and a small subset of patients live a decade or longer with anaplastic astrocytoma or rarely, with glioblastoma. Prognosis is influenced by patient factors, such as age and functional status, as well as tumor-related factors such as grade, location, extent of resection, and molecular determinants such as the presence of IDH1/IDH2 mutation and MGMT promoter methylation. Older literature correlates increased survival in high-grade astrocytomas with codeletion of chromosome 1p and 19q, but these molecular changes are now recognized to be markers of a different disease, oligodendroglioma. The best prognosis is generally found among young, otherwise healthy, patients with a gross total resection and MGMT methylation and IDH1/IDH2 mutation, but even in these cases, the tumor inevitably recurs. In light of the significant morbidity and mortality from anaplastic astrocytoma and glioblastoma, there is a desperate need for improved treatment in this disease.

OLIGODENDROGLIOMAS

Introduction

Oligodendrogliomas are diffusely infiltrating gliomas composed of neoplastic cells that morphologically resemble oligodendrocytes. Although these tumors exist on a continuum from well differentiated to overtly malignant, they are categorized into two distinct prognostic groups: low-grade WHO grade II diffuse oligodendrogliomas and high-grade WHO grade III anaplastic oligodendrogliomas. As opposed to astrocytomas, there is no WHO grade IV oligodendroglioma. Molecularly, oligodendrogliomas are associated with the presence of *IDH* mutation and codeletion of chromosome arms *1p* and *19q*. These tumors are significantly more chemo- and radiosensitive than their astrocytic counterparts and are generally associated with a more indolent disease course.

Epidemiology

Oligodendrogliomas make up about 5% of all gliomas and the vast majority are WHO grade II tumors. The median age at diagnosis for all oligodendrogliomas is 43 years, with WHO grade III tumors occurring at slightly older age. These tumors are rare in children.

Pathobiology

The majority of oligodendrogliomas in adults display mutations in *IDH1* or *IDH2*, suggesting that the oncometabolite 2-hydroxyglutarate plays a role in development of these tumors from precursor cells. As opposed to IDH-mutant astrocytomas, *IDH* mutation in these tumors usually coexists with codeletion of chromosomes 1p and 19q as well as *TERT* promoter mutations. Interestingly, given the relatively indolent nature of oligodendrogliomas, *TERT* promoter mutations are also the hallmark of the most aggressive high-grade glioma, IDH wild-type glioblastoma. How the same genetic alteration can be associated with such divergent disease courses remains unclear.

Oligodendrogliomas preferentially arise in the cortex and subcortical white matter of the cerebral hemispheres, most frequently in the frontal lobe. Approximately two-thirds of patients present with seizures, although headache or focal deficits are also common. Anaplastic oligodendrogliomas can arise de novo or as

FIGURE 100.5 Low-grade oligodendroglioma (WHO grade II). Gadolinium contrast–enhanced T1- **(A)** and T2-weighted **(B)** MRI of a patient with a largely nonenhancing infiltrative oligodendroglioma.

a result of progression from a WHO grade II oligodendroglioma, on average 6 to 7 years after initial diagnosis.

Diagnosis

On MRI brain oligodendrogliomas are classically T2/FLAIR hyperintense and infiltrative mass lesions without distinct borders (**Fig. 100.5**). Low-grade WHO grade II diffuse oligodendrogliomas are generally nonenhancing, whereas high-grade WHO grade III anaplastic lesions frequently have some degree of enhancement. Calcification is characteristic of oligodendrogliomas, although this finding is not specific.

Definitive diagnosis of an oligodendroglioma requires tissue sampling. On histology, oligodendrogliomas are composed of monomorphic cells with round nuclei and characteristic perinuclear halos that give it an appearance of "fried eggs" in a dense "chicken wire" network of branching capillaries (**Fig. 100.6**, panel A). WHO grade II diffuse oligodendrogliomas may have marked cellular atypia and occasional mitoses, but significant mitotic activity, necrosis, or microvascular proliferation indicates a diagnosis of WHO grade III anaplastic oligodendroglioma (**Fig. 100.6**, panel B).

The majority of oligodendrogliomas display mutations in IDH1 or IDH2 that can be identified by immunohistochemistry for *IDH1 R132H* or by genetic sequencing for noncanonical mutations. Loss of the short arm of chromosome 1 (1p) and the long arm of chromosome 19 (19q) on fluorescence in situ hybridization or comparative genomic hybridization (ie, 1p/19q codeletion) is a hallmark of these tumors and used to distinguish IDH-mutant oligodendrogliomas from IDH-mutant astrocytomas. *MGMT* promoter methylation status is commonly used as a prognostic indicator in WHO grade III anaplastic oligodendrogliomas, but its role in low-grade oligodendrogliomas is not clear.

Oligodendrogliomas that lack IDH-mutation are exceedingly rare but occasionally encountered in children. In these cases, lack of an IDH mutation should prompt consideration of alternate diagnoses.

FIGURE 100.6 Oligodendroglioma. **A:** Hematoxylin and eosin–stained section of a WHO grade II oligodendroglioma. Note the characteristic perinuclear halos given the appearance of "fried eggs." The adjacent WHO grade III anaplastic oligodendrogliomas **(B)** displays increased hypercellularity, marked nuclear atypia, frequent mitoses *(arrows)* and microvascular proliferation *(yellow arrowhead)*. Management

Management of WHO Grade II Diffuse Oligodendrogliomas

The indolent but incurable nature of low-grade oligodendrogliomas makes management quite nuanced and requires a balance between efforts to extend lifespan and the preservation of neurocognitive function. Surgery is generally recommended for all patients with a goal of maximal safe resection of all T2/FLAIR hyperintense disease. Surgery is not curative because these tumors tend to infiltrate significantly past the visible radiographic margin. However, the timing of adjuvant RT and chemotherapy varies based on patient characteristics and extent of resection.

In patients younger than the age of 40 years with confirmed WHO grade II diffuse oligodendroglioma who underwent gross total resection, it is possible to delay adjuvant chemoradiation and monitor clinically. This recommendation is partly based on the observation that immediate RT delays progression-free survival in LGG patients but does not alter overall survival compared to delayed radiation LEVEL 1.[1] Thus, this strategy aims to delay the neurotoxicity of adjuvant RT without affecting survival. Given the ultimately incurable nature of these tumors, current guidelines also advocate for enrollment into clinical trials even for these low-risk patients.

In patients older than 40 years of age, or after subtotal resection, immediate adjuvant RT, and chemotherapy is almost always indicated. As with IDH-mutant astrocytomas, combination therapy is recommended given evidence from the RTOG 9802 trial of radiotherapy followed by chemotherapy with PCV, which demonstrated a survival benefit of 13.3 versus 7.8 years in LGG patients LEVEL 1.[4] Temozolomide also has activity against these tumors and is commonly used given its better tolerability compared to PCV, but there is no published data directly comparing it to PCV.

Management of WHO Grade III Anaplastic Oligodendrogliomas

Anaplastic oligodendrogliomas behave more aggressively than their low-grade counterparts and require early intervention. Following the paradigm for high-grade astrocytomas, maximal safe resection is immediately followed by RT and chemotherapy, although data is lacking to determine the optimal regimen. RTOG 9402 compared RT alone to RT with sequential PCV in patients with WHO grade III anaplastic oligodendroglioma and did not show a survival benefit to combination therapy. However, the study defined oligodendrogliomas exclusively on the basis of histology, rather than their molecular signature. A post hoc analysis of patients stratified by 1p/19q codeletion showed that patients with 1p/19q codeleted tumors (ie, what we now define as oligodendrogliomas) who received combination chemoradiation had a median survival twice as long as those who received RT alone, whereas those without 1p/19q codeleted tumors derived no benefit LEVEL 1.[17] The ongoing CODEL trial (Alliance-N0577, European Organisation for Research and Treatment of Cancer (EORTC)-26081/2208, NRG-1071, NCIC-CEC-2) initially looked to compare survival in patients treated RT and temozolomide versus temozolomide alone, but the temozolomide monotherapy was closed due to concerns regarding decreased progression-free survival. Currently, the CODEL trial is directly comparing RT with sequential PCV to RT with concurrent and adjuvant temozolomide, but until results are published, the comparative effectiveness of PCV or temozolomide in this disease remains unknown.

Options for management of recurrent oligodendroglioma are limited regardless of grade. Re-resection or reirradiation can be considered in select patients depending on the location and timing of the recurrent tumor. In addition, both temozolomide and PCV have been shown to have activity at the time of recurrence. Other agents with some minor evidence of activity include paclitaxel, irinotecan, carboplatin, and etoposide. Bevacizumab may also have a palliative role in recurrent oligodendroglioma as in high-grade astrocytomas, but its effect on overall survival is unclear.

Outcome

Despite their relatively indolent nature compared to astrocytomas, oligodendrogliomas invariably recur and are not considered curable tumors. Data for median survival predates the use of 1p/19q codeletion for diagnosis, which is known to be a strong positive prognostic indicator. WHO grade II diffuse oligodendroglioma as defined by histology is associated with a median survival of about 10 years and a 5-year survival of 81.6%, compared to approximately 5 years and 57.6% survival for WHO grade III anaplastic oligodendroglioma. Presence of an IDH mutation and 1p/19q codeletion as well as more aggressive care with combination chemoradiation likely portend better outcomes than this historical data, but how much is unclear.

Metastatic Tumors 101

Rupesh Kotecha and Minesh P. Mehta

KEY POINTS

1. Brain metastasis in the modern era should be managed in a multidisciplinary approach to ensure optimal timing of local and systemic therapies.
2. Radiation therapy treatment options include whole brain radiotherapy, stereotactic radiosurgery, and hippocampal-avoidance whole brain radiotherapy.
3. Targeted agents and immunotherapies have revitalized the role of systemic therapy in patients with newly diagnosed or recurrent brain metastases.
4. Resection remains the first approach in patients with large, symptomatic metastasis but can also be performed in patients who need pathologic confirmation or re-evaluation of tumor biology or molecular profile.

INTRODUCTION

It is estimated that today, in the United States, there are over 15.5 million people living with a diagnosis of cancer, and the American Cancer Society projects that more than 1.7 million new cancer diagnoses will occur in 2019. The American Society of Clinical Oncology predicts that cancer will overtake heart disease as the most common cause of death by 2030, and it is already the leading cause of death in Americans younger than 85 years of age. Metastatic disease, that is, cancer that has spread from its site of origin (from the Greek *meta*, meaning "next," and *stasis*, meaning "placement"), is the cause of death in the vast majority of cancer patients. This chapter provides a general overview of central nervous system (CNS) metastasis followed by an extensive review of specific clinical entities, including brain metastasis, epidural spinal column metastasis, and leptomeningeal metastasis (LM).

OVERVIEW OF METASTATIC TUMORS

Epidemiology

Although the number of new cases of metastasis to the CNS diagnosed annually is estimated at over 200,000, the exact incidence remains unknown. The reason for this is that although cancer as a disease is reportable, sites of metastatic disease are not routinely recorded in any registry. Autopsy studies have reported the presence of intracranial metastases in approximately 10% to 30% of all cancer patients (15% to the brain, 5% to the leptomeninges, and 5% to the dura) as well as occult LM in approximately 20% of cancer patients. The incidence of brain metastasis has risen steadily over the last few decades, a phenomenon that is likely multifactorial: Guidelines for systemic staging of cancer have now incorporated imaging of the brain for a variety of cancers, clinical trial entry often precludes a diagnosis of brain metastasis resulting in more frequent screening, high-resolution imaging allows smaller brain metastasis to be detected, and increasingly effective treatments lead to prolonged survival and thus a longer period during which CNS metastases may develop. One conjectured reason for the very high incidence of metastatic disease to the brain is the highly selective permeability of the blood-brain barrier (BBB), which allows tumor cells sanctuary in the CNS both from immune surveillance and the cytotoxic effects of chemotherapy because most of these agents fail to penetrate the barrier adequately.

Although the brain parenchyma, especially the gray-white junction, is the location most likely to be involved (80%) with metastatic disease to the CNS, other common sites include the epidural space and leptomeninges. Less common sites include the dura, intramedullary spinal cord, optic apparatus, and other cranial and peripheral nerves. Data regarding these less common sites are generally limited to case reports and small series, and therefore, this discussion focuses on CNS metastases, primarily of the parenchymal brain.

Pathobiology

The molecular processes within cancer cells and their microenvironment that ultimately result in the development of metastatic disease are poorly understood and are the focus of much ongoing research. It is known that the spread of tumor cells into systemic circulation is an early phenomenon in the natural history of malignancy, but these circulating tumor cells do not always lead to metastasis. It is estimated that less than 0.01% of these cells are able to establish a metastatic lesion at a distant anatomic site. This could well be a consequence of immune surveillance mechanisms. It is also known that certain malignancies have a predilection to metastasize to particular organs. This may be due in part to simple anatomic considerations, such as venous drainage patterns, sites of first "entrapment", etc, but may also be dependent on specific molecular characteristics, including the secretion of specific chemotactic factors by the organ or site involved. Neurotropic growth factors in the CNS are thought to play such a role. Another possible factor is the expression of specific surface molecules on tumor cells that allow them to "home" to certain tissues. Preliminary data suggest that melanoma cells possess such molecular features, which allow them to have among the highest probabilities of metastasizing to the brain. In fact, recent emerging molecular characterization data suggest that when primary tumors, extracranial metastases, and intracranial metastases are interrogated at a molecular genetic level, metastases to the CNS are distinctly different, both from the primary tumor, as well as extracranial metastases, further lending credence to the emerging hypothesis that only cells that develop certain physiologic capabilities through unique mutations are able to metastasize to the CNS.

Possible pathways for spread of cancer include hematogenous, lymphatic, intrathecal, and perineural (Fig. 101.1). Although not technically metastatic, tumors may directly extend

FIGURE 101.1 Routes of metastases. Abbreviation: CSF, cerebrospinal fluid.

into neighboring structures, including the CNS. For example, tumors of the head and neck may invade the brain or spinal cord by direct extension of disease through the base of skull. The intravasation of the cancer cell requires multiple signals between that cell and its surrounding microenvironment. Some data suggest that transformation of the malignant cell into a mesenchymal, or connective tissue–like, state is crucial for this, a phenomenon referred to as *epithelial-to-mesenchymal transition*.

Once intravasated and in circulation, normal anatomic organs may act as a barrier to tumor spread. Regional lymph nodes may trap tumor cells. The hepatocytes of the liver filter the blood as the venous return from abdominal organs passes through them; therefore, the liver is a frequent site of metastatic disease from gastrointestinal tract tumors. The BBB presents another obstacle for circulating tumor cells. Logically, organs with large volumes of blood flow are more prone to metastatic disease, such as the pulmonary capillary bed with its high flow. The CNS and bones receive approximately 20% of cardiac output; it is therefore not surprising that the liver, lung, CNS, and bones are the most common sites of metastatic disease.

When cancer cells arrive at a distant site, they must extravasate from circulation and establish growth at this new location, a complex process that requires multiple interactions with the new microenvironment. The nascent metastasis must also be capable of angiogenesis, the formation of new blood vessels, in order to sustain growth larger than approximately 1 mm. Despite all these required steps for the formation of distant metastases, metastatic disease from cancer is an all too real and common phenomenon, indicating that this orchestrated process of dissociation, intravasation, circulation, avoidance of immune surveillance, extravasation, and metastatic growth is efficiently coordinated by a significant number of malignancies through sophisticated genetic interplay.

Diagnosis

Metastatic disease to the CNS may present with or without symptoms, and an appropriate clinical workup is necessary to confirm the diagnosis. In asymptomatic patients, metastatic disease is often found incidentally during cancer workup and staging or while concomitant nonmalignant comorbidities are investigated. CNS metastasis is often diagnosed in the context of a known history of malignancy, but symptomatic CNS metastasis may also be the initial clinical presentation of a previously unidentified malignancy. In this situation, biopsy or resection may be required in order to pathologically confirm a diagnosis of cancer and guide treatment. The most common primary malignancy that presents with metastatic disease in the brain is lung cancer (Fig. 101.2). The most common primary malignancies that present with metastatic disease to the spine are breast and prostate cancer. In some cases, the primary malignancy responsible for the metastatic disease is never identified despite a complete and thorough evaluation.

History and Physical Examination

The clinical presentation of CNS metastasis is highly dependent on the specific neurologic structures involved and the degree to which they have been compromised. Symptoms may be of gradual or abrupt onset, which provides insight not only to the underlying pathologic processes but also to prognosis and likelihood of recovery. Clinical workup of a new neurologic deficit begins with a thorough history and physical exam, with particular focus on the elucidation of any neurologic deficits.

Laboratory Studies

Blood work has limited use in the workup of CNS metastatic disease, but one exception is tumor markers: cancer-specific or cancer-associated proteins that are measurable in the blood or cerebrospinal fluid (CSF). If these markers are elevated, especially in the CSF, then systemic metastases, including neurologic, are more likely. The converse statement, however, is not true in that normal tumor marker values do not preclude malignancy or metastatic disease. Despite this limited use, any patient with general neurologic symptoms, such as altered mental status, headaches, or seizures, should have basic testing obtained in order to rule out other etiologies such as infection, electrolyte imbalance, toxins, or blood gas abnormalities.

Imaging

Magnetic resonance imaging (MRI), with and without gadolinium contrast, is the gold standard imaging modality for patients with suspected CNS disease. Computed tomography is used in patients who cannot tolerate MRI and occasionally to further evaluate

FIGURE 101.2 Estimated incidence risk of development of brain metastasis by primary tumor site.

hemorrhage; it also has value in the rare situations where the brain metastases is a consequence of a metastatic focus in the bones of the skull with direct extension intracranially. Magnetic resonance spectroscopy can suggest whether a lesion is neoplastic, inflammatory, or other. At present, positron emission tomography with ^{18}F-fluorodeoxyglucose has limited use in evaluation of brain metastases due to the high background activity of the normal brain. Novel positron emission tomography tracers are in an exploratory phase. It is important to note that none of these imaging techniques replaces histology for diagnostic accuracy.

Tissue Diagnosis

In many cases, histologic confirmation of a CNS metastasis is unnecessary, as the likelihood of metastatic disease from a known primary, especially in the setting of known metastatic disease, outweighs the likelihood of a new primary CNS tumor. This is particularly true if imaging studies demonstrate characteristic features of metastatic disease. In other cases, the diagnosis of CNS metastasis is unclear despite the history, physical exam, laboratory values, and radiographic studies. If the diagnosis of metastatic disease is in question, and if the lesion is surgically accessible with reasonable safety, biopsy, or resection should be performed to provide histopathologic diagnosis.

Another important possible method of identifying metastasis to the CNS is sampling of the CSF with a lumbar puncture (LP). LP may also rule in or out other etiologies and clarify the diagnosis of LM (also termed *leptomeningeal carcinomatosis*, *neoplastic meningitis*, or *carcinomatous meningitis*). It will not, however, diagnose parenchymal brain metastases in the absence of CSF involvement. LP is contraindicated due to the risk of brain herniation in cases where increased intracranial pressure (ICP) is suspected.

Management

Both symptomatic and definitive treatments must be addressed in a patient who presents with metastatic disease to the CNS. Symptomatic treatments include corticosteroids, medications for seizure management, and anticonvulsant prophylaxis. Definitive treatments include surgery, radiation therapy (RT), and systemic therapy (chemotherapy, targeted therapies, or immunotherapy).

Corticosteroids and Antiepileptics

Metastatic disease may cause marked edema due to extravasation of plasma from leaky tumor vasculature. Within the narrow anatomic confines of the CNS, this edema may cause increased ICP and significant compression of normal neural tissue (Fig. 101.3A). Symptoms of increased ICP include headaches and blurred vision. Corticosteroids, most commonly dexamethasone, should be given immediately to symptomatic patients and often result in rapid improvement in symptoms. One widely used dosing of corticosteroids begins with an intravenous bolus of 10 mg of dexamethasone (although the actual value of the intravenous route over oral as well as the larger 10-mg dose, in terms of symptom resolution is unclear), followed by 4 mg given every 6 hours. The dose should be rapidly titrated upward or downward as needed. Large doses can cause acute psychiatric symptoms, and chronic administration has a myriad of toxicities including candidiasis, increased risk of pneumocystis pneumonia, metabolic imbalance, sleep and mood disturbance, muscle atrophy and wasting, weight gain, osteopenia and pathologic fractures, gastrointestinal irritability, and perforation. Corticosteroids should be tapered as rapidly as tolerated once definitive therapy has been initiated.

Symptomatic patients or those with radiographic evidence of significant mass effect should be stabilized with corticosteroids as soon as possible. Corticosteroids have been shown to improve or resolve symptoms in up to two-thirds of patients and may confer a small survival benefit compared to no treatment. In select patients with an extremely poor performance status and short expected survival, symptomatic management alone with corticosteroids can be considered LEVEL 1.[1] Patients who present with seizures should be stabilized with antiepileptic medications, preferably selecting agents that do not induce cytochrome p450 hepatic enzymes because such induction could interfere with metabolism of some chemotherapies or corticosteroids. Antiepileptics are generally not indicated in patients without a prior history of seizure because they have no proven benefit when given prophylactically and may have significant adverse effects, including fatigue and decreased cognition; however, studies suggesting antiepileptics have risk outweighing benefit in seizure naïve patients were

conducted before some of the more modern drugs, such as levetiracetam, were developed, and definitive data are lacking in the modern era LEVEL 1.[2]

Surgery

In general, surgical management is considered for patients who are medically fit, with large tumors (>2-3 cm), one or few tumors, and/or disease associated with significant brain swelling, mass effect, and neurologic deficits. The benefits of direct tumor removal with surgery include rapid improvement in symptoms and improved local disease control. The decision for or against surgery depends on many factors, including overall clinical performance status of the patient; status and extent of systemic disease; and location, size, and number of intracranial metastases. Surgery should be followed by adjuvant RT or, less commonly, chemotherapy. Risks of surgery include bleeding, infection, CSF leak, and transient or permanent neurologic deficit.

Radiation Therapy

RT may be used in combination with surgery, typically as adjuvant therapy following maximal resection or as primary therapy for unresected disease. Tumor regression following RT is a gradual process, and the therapeutic effects lack the immediacy of resection, making RT second-line therapy in situations where immediate decompression is indicated.

For patients with known brain metastases too numerous to target individually, RT is generally delivered to the entire brain (whole brain radiation therapy [WBRT]) with the rationale that the presence of brain metastases indicates that the entire organ has been compromised. The likelihood of other tumor cells with metastatic potential elsewhere within the brain is high, and WBRT may not only treat the known lesions but may also prevent or delay the development of macroscopic disease elsewhere in the brain.

WBRT alone may reduce or eliminate symptoms from brain metastases in 60% to 80% of patients and may result in a significant radiographic response in about half of all patients. WBRT is also associated with improved median survival 4 to 6 months as opposed to 1 month without treatment. Side effects include fatigue, headaches, alopecia, neurocognitive decline, radiation necrosis, and damage related to the specific area of the brain being irradiated.

In the United States, WBRT is classically given to a total dose of 30 Gy delivered in 10 fractions, although several other fractionation schedules have been shown to have similar efficacy with no significant difference in toxicity (20 Gy in 5 fractions, 30 Gy in 15, 37.5 Gy in 15, 40 Gy in 15, and 40 Gy in 20). Doses higher than this (≥50 Gy) and hyperfractionation (more and smaller fractions) did not show a survival benefit, and larger fraction sizes were found to be detrimental, with shorter progression-free survival and higher neurologic toxicity LEVEL 1.[3-5]

Recently, clinical trials have focused on attempting to decrease the cognitive dysfunction associated with WBRT, and at least two approaches, the addition of the *N*-methyl-D-aspartate-receptor agonist, memantine, and the deliberate reduction of dose to the hippocampi have both been shown in randomized trials to produce meaningful cognitive benefit, and these techniques are now rapidly being incorporated into routine clinical practice.

Prophylactic cranial irradiation (PCI) is when WBRT is administered in the absence of known macrometastatic disease in the brain in order to decrease the likelihood of developing brain metastasis. PCI is indicated in small cell lung cancer,

which has a very high propensity for brain metastasis, and reduces the risk of subsequent intracranial failure and also improves survival LEVEL 1.[6,7] Other tumors, particularly classic pediatric brain tumors such as medulloblastoma, have a high incidence of metastatic disease to not only elsewhere in the brain but also throughout the craniospinal axis, and prophylactic craniospinal irradiation is given to the entire CNS axis in these situations.

Stereotactic radiosurgery (SRS) is a more targeted RT technique in which a much larger dose of radiation is given, generally in a single treatment. The advantages of SRS include shorter treatment time (1 d vs 2-3 wk), rapid reinitiation of systemic therapy, and decreased radiation dose to the surrounding normal brain tissue. SRS may be used safely to treat multiple brain lesions and may also be given in combination with WBRT. In certain situations, the precision of SRS is combined with the delivery of a few large fractions of radiation, as opposed to a single fraction, an approach referred to as *stereotactic radiotherapy*. This is most often performed for metastases close to sensitive structures or for those too large (>2-3 cm) for effective single fraction treatment without significant morbidity.

Chemotherapy

Chemotherapy has traditionally had a limited role in the treatment of CNS metastases because the BBB and blood-CSF barrier inhibit the ability of systemic agents to penetrate to the brain and spinal cord. Some agents with good CNS penetration include high-dose intravenous methotrexate and temozolomide. Chemotherapy may also be administered intrathecally, typically via a port placed into the ventricular system, which helps circumvent these natural anatomic barriers, but intrathecal chemotherapy (ITC) only penetrates into brain parenchyma by a few millimeters at most and is generally ineffective against most parenchymal brain metastases. Another limitation to using chemotherapy to treat neurologic metastasis is that the primary malignancy might have previously been treated with the same agent, leading to acquired resistance. Finally, mutations in the primary tumor may differ from intracranial metastases, also rendering systemic therapy less effective against these sites of metastatic disease.

Cancer histologies for which chemotherapy has shown efficacy, albeit modest, in CNS metastases include germ cell tumors (where the effect is dramatic), small cell lung cancer (where the effect can be rapid, but often of limited durability), and breast cancer. Cancers harboring specific driver mutations such as epidermal growth factor receptor (EGFR) mutations or anaplastic lymphoma kinase (ALK) rearrangements in non–small cell lung cancer (NSCLC), *BRAF* mutations in melanoma, etc, may respond well to appropriate targeted therapeutics (eg, EGFR tyrosine kinase inhibitors, ALK inhibitors, BRAF inhibitors), as newer next-generation targeted drugs do at least partially penetrate the BBB.

BRAIN METASTASIS

Epidemiology and Clinical Manifestations

The most common type of cancer of the brain is metastatic disease; brain metastases outnumber primary brain tumors by a ratio of approximately 10:1. Up to 20% to 40% of all cancer patients will develop metastatic disease to the brain at some point during the course of their systemic disease. The brain may be a site of relapse at any time in the patient's clinical course, but the median time interval between the primary cancer diagnosis and development of brain metastasis is approximately 1 year, but the interval range can exceed 10 years. NSCLC is the most common source of brain metastases. In comparison, a larger proportion of patients with diagnoses such as melanoma, small cell lung cancer, renal cell carcinoma, and specific subsets of breast cancer will develop brain metastases, but due to the lower number of patients diagnosed with these diseases, the total incidence from these primary tumors is lower than that from NSCLC.

Symptoms of CNS metastases result from both focal pressure on surrounding tissue, destruction of normal neurons, and global increases in ICP from the metastases or associated peritumoral edema. Presenting symptoms most often include headache (49%), altered mental status (32%), focal weakness (30%), ataxia (21%), and seizures (18%). Diffuse, small, miliary lesions scattered throughout the brain parenchyma are particularly associated with leukemia and small cell lung cancer and may manifest as a generalized encephalopathy (**Fig. 101.3B**).

Untreated brain metastases generally produce worsening symptoms over days to weeks. In some cases, symptoms are more acute and may mimic ischemic or hemorrhagic stroke. The more abrupt clinical course may particularly be seen with bleeding within the metastasis; hemorrhagic brain metastases are classically associated with certain histologies, including melanoma, renal carcinoma, choriocarcinoma, NSCLC, and thyroid (**Fig. 101.3C**).

Diagnosis

In the setting of a known diagnosis of cancer and new neurologic symptoms, multiple, spheroidal, enhancing brain lesions, mostly at the gray-white junction, with a disproportionate degree of edema on MRI, strongly suggest a diagnosis of brain metastases. Differential diagnosis includes primary brain tumor, lymphoma, abscess, other infectious processes, stroke, multifocal demyelination, or radiation necrosis. A seminal series of 54 patients, all with a prior history of an invasive malignancy, with a new single brain lesion seen on imaging who underwent resection or biopsy reported pathologic discordance in 11%; in other words, 1 of 10 patients with MRI findings consistent with a single metastatic lesion in the brain might not have a brain metastasis.

Brain metastases may be single or multiple. The classic appearance of metastatic disease in the brain is a round, irregular, ring-enhancing lesion at the gray-white matter interface with associated vasogenic edema (**Fig. 101.3D**). In comparison, high-grade gliomas are most commonly single and rarely present as multiple distinct lesions and may appear more infiltrative and irregularly shaped than brain metastases. Primary CNS lymphoma tends to present as periventricular, homogenously enhancing disease. Intracranial abscesses are high on the list of differentials in the setting of immunosuppression. These appear as well-circumscribed, thick-rimmed, ring-enhancing masses with central hypodensity. Stroke, both hemorrhagic and ischemic, may produce both similar symptoms and imaging findings as brain metastases. Multifocal demyelination has been reported after treatment with certain chemotherapy agents (5-fluorouracil and levamisole) and may also mimic metastases in appearance. Radiation necrosis is a known potential complication from RT, particularly SRS, and may also appear as a contrast-enhancing mass (**Fig. 101.3E**).

About 80% of brain metastases involve the cerebral hemispheres, 10% the cerebellum, and 5% the brainstem, a rate of incidence that appears consistent with the relative volume and percentage of intracranial blood flow. A high proportion of brain metastases are seen in the watershed regions. This is most likely due to smaller blood vessels and slower blood flow in these areas. For reasons that are not fully understood, different histologies may preferentially metastasize to different brain locations. For example, lung cancer tends to metastasize to the cerebrum, whereas gastrointestinal malignancies tend to metastasize to the cerebellum.

Management

Approximately 30% to 50% of patients with metastatic disease to the brain will die from progressive intracranial disease. Therefore, when considering treatment options, one must consider not only the extent of intracranial disease but also overall disease burden, clinical status, and prognosis. To predict survival in the setting of intracranial metastasis, the Radiation Therapy Oncology Group (RTOG) developed a recursive partitioning analysis classifier that stratified patients based on performance status, age, control of primary tumor, and presence of extracranial metastatic disease. Subsequently, the Graded Prognostic Assessment index was developed as a more objective prognostic scoring system and incorporated additional variables such as the number of brain metastases, with further iterations being histology specific and the most recent versions incorporating molecular markers. Based on these classification schemes, predictions may be made regarding overall survival, which may then be used to potentially guide therapy decisions.

Two clinical scenarios merit additional clarification: (1) a single brain lesion, meaning known disease elsewhere with only one lesion in the brain, and (2) a solitary brain lesion, meaning the one metastasis to the brain is the only known site of disease. (It should be noted that the literature often uses single and solitary interchangeably.) Single or solitary brain lesions generally warrant aggressive management because this may have a significant impact on survival. Several series have reported that treatment of single, synchronous brain metastases from NSCLC in addition to definitive thoracic treatment improved survival.

After medical stabilization, definitive treatment with surgery, focused RT with SRS or WBRT, chemotherapy (including targeted agents in highly selected patients), or different combinations of these modalities are considered. The only clinical trials that have ever demonstrated survival advantage from more aggressive therapy are in patients with single (inclusive of solitary) brain metastasis.

Focal Treatment

Brain metastases may be focally treated with either surgery or SRS. After resection of a brain metastasis, patients undergo either SRS or WBRT, to improve the rate of local disease control LEVEL 1.[8]

Surgery

Resection of a limited number of brain metastases, usually one, results in improved outcomes, both for locoregional recurrence and overall survival. Resection alone, however, is not adequate and results in a high risk of local failure (Fig. 101.4). For patients with solitary or single brain metastases with controlled systemic disease, resection followed by WBRT prolongs survival (median 40-50 weeks), functional independence, and improved neurologic function versus WBRT alone LEVEL 1.[9] Appropriate patient selection is crucial because resection of single metastases in patients with a greater burden of systemic disease or with poorer performance status generally does not lengthen survival. This is believed to be the reason behind the lack of survival benefit seen in the trial by Mintz et al because this study included patients with Karnofsky performance status of 50, compared to minimum Karnofsky performance status of 70 for patients enrolled in the other two trials LEVEL 1.[10] The results of this trial were also potentially confounded by a high rate of surgery following disease progression among patients randomized to WBRT alone. As an alternative to adjuvant WBRT, patients with limited brain metastases who undergo resection of one or more lesions can also undergo postoperative SRS to the resected metastases as well as definitive SRS to the remaining lesions. This approach results in similar survival rates yet reduced decline in neurocognitive function, compared to WBRT, at the cost of increased focal brain necrosis and a substantially elevated risk of failure in the rest of the brain, including the leptomeninges LEVEL 1.[11] Table 101.1 summarizes the key randomized surgical and RT trials LEVEL 1.[9,10,12-14]

Patient ultimately experienced a local recurrence in the postoperative bed **(C)** as well as numerous intracranial metastases necessitating salvage whole brain radiotherapy **(D)**.

Surgery is preferred to radiation in the setting of extensive edema and increased ICP because it is the most efficacious therapy for immediate reduction of mass effect. Surgery is also preferred for cases in which a pathologic sample is desired to guide

Abbreviations: NS, not significant; SRS, stereotactic radiosurgery; WBRT, whole brain radiation therapy.

treatment and for lesions larger than 4 cm. Wider application of surgery is limited by the risk of morbidity, particularly for multiple metastases for which multiple craniotomies might be necessary. Retrospective studies of resection of up to two metastases in well-selected patients suggest a possible survival advantage, but level 1 evidence to support this approach is lacking. Although no randomized trials have explored the role/value of multiple craniotomies for multiple metastases, in clinical practice, patients presenting with multiple large metastases with considerable mass effect and imminent herniation might be best served by undergoing such an approach because neurosurgical techniques, risks of anesthesia, and neurointensive care unit recovery processes have dramatically improved over the last decade, permitting safe application of such a radical approach (Fig. 101.5).

Stereotactic Radiosurgery

SRS is used to deliver a single, high-dose treatment of RT to a small, well-circumscribed target and is frequently used for metastatic disease that is not amenable to surgery due to location or to patient comorbidities. Unlike surgery, SRS may be considered in the treatment of multiple lesions. SRS results in either stability or decrease in tumor size in over 80% of patients and represents an effective means to achieve local control. With submillimetric treatment precision accomplished with increasingly sophisticated immobilization and imaging and extremely sharp dose gradients, SRS is capable of safely delivering high doses of radiation to the target with markedly reduced dose to neighboring sensitive structures. This capability for dose escalation means that metastases from radioresistant histologies, such as melanoma and renal cell carcinoma, are more likely to be controlled. The prescribed dose of RT delivered by SRS is determined by the size of the lesion, with larger lesions receiving lower doses due to the increased risk of inducing unacceptable edema and radiation necrosis. Also for this reason, the largest lesion that may be safely treated with single-fraction SRS is on the order of 3 to 4 cm, although lesions up to 5 cm in size have been treated with

FIGURE 101.5 **A:** Patient with four large cystic brain metastases in the left cerebellar, right temporal, right frontal, and right parietal regions. **B:** Given the size and cystic nature of the lesions, all were successfully resected prior to adjuvant radiotherapy with rapid symptomatic improvement.

diminishing local control. Newer methods of delivering SRS, such as a staged approach (one dose followed by an interval of 2-4 wk followed by a boost dose) as well as the incorporation of stereotactic radiotherapy (treatment delivered over 3-5 fractions) into clinical practice have allowed for larger lesions to be treated with these high-precision RT techniques.

SRS is sometimes used in combination with WBRT. A randomized trial compared WBRT plus SRS to one to three brain metastases versus WBRT alone and found an overall survival advantage with the addition of SRS in patients with a single lesion; on post hoc analysis, other subgroups with survival benefit were identified and included patients with lung cancer with up to three lesions and RTOG recursive partitioning analysis class I patients LEVEL 1.[15]

An active area of investigation is the use of SRS to prevent local recurrence postresection. Resection bed SRS is more complex than targeting an enhancing tumor due to uncertainties regarding the interpretation of a postoperative MRI. One series reported a 1-year local control rate of 94% when a 2-mm margin was added around the defined tumor bed versus 78% when no margin was added and another suggested that most tumor bed recurrences occurred within 3 mm from the resection cavity. Consensus guidelines help to define important principles when delineating the target volume at the time of SRS planning. One concern regarding surgical bed SRS is the possibility of leptomeningeal spread secondary to the resection, especially for patients with large lesions, those that are dural based, those in patients with specific subtypes of breast cancer, and in those with posterior fossa disease. A second concern is that tumor beds "fill-up" postoperatively with normal brain tissue, and especially when margins are employed, a lot of brain parenchyma would receive high radiation doses, increasing the likelihood of necrosis. The North Central Cancer Treatment Group, in collaboration with RTOG, recently reported on a randomized study, which compared postoperative WBRT versus resection bed SRS. Patients who received postoperative SRS experienced higher rates of cognitive deterioration–free survival but no difference in overall survival, and a significantly elevated incidence of intracranial relapse LEVEL 1.[11] Some institutions use preoperative SRS to obviate the tumor bed definition challenges and contend that the leptomeningeal dissemination rate is lower, tumor control is higher, and radiation necrosis risk is lower, but no prospective evaluations of pre- versus postoperative SRS have been conducted to date.

Whole Brain Radiation Therapy in Addition to Focal Treatment

Although focal therapy, such as surgery or SRS, can effectively control the treated lesion, the rate of relapse in the rest of the brain is still approximately 30% to 70%. WBRT following resection or SRS of a single (or up to four) brain metastases yields improvement in local control, reduction in distant intracranial failure, and reduction in death from neurologic progression. The addition of WBRT to focal treatment unquestionably reduces intracranial relapse, but cognitive decline consequential to the late effects of WBRT may occur in a significant proportion of patients. Neurocognitive effects may be seen within months, and fixed deficits become pronounced years after treatment. Half or more of all patients with brain metastases die from systemic progression rather than from their intracranial disease, but certainly, some patients have prolonged survival and clinicians must therefore consider and discuss the possible late complications of WBRT. Recent data support a protective effect for the drug memantine LEVEL 1.[16] Sparing critical structures within the brain, such as the perihippocampal regenerative subgranular stem cell niche, during radiotherapy planning also reduces the development of neurocognitive deficits from WBRT. A recent randomized trial of conventional WBRT and memantine compared with hippocampal avoidance WBRT (an advanced radiotherapy treatment technique in which the entire brain parenchyma is treated to a therapeutic dose but the bilateral hippocampal regions receive reduced doses) and memantine showed a longer time to neurocognitive failure with hippocampal avoidance WBRT, supporting its role in routine clinical practice LEVEL 1.[17]

SRS is increasingly used alone, particularly in elderly patients or others with fragile baseline mentation or in those whose overall prognosis is excellent. In one small randomized trial, SRS alone actually produced neurocognitive preservation superior to WBRT plus SRS; however, the small trial size resulted in concerns regarding patient selection imbalance LEVEL 3.[18] In a larger Japanese trial, cognitive function, as measured using the Mini-Mental State Examination trended toward superiority for the SRS + WBRT arm, with a longer period to Mini-Mental State Examination decline favoring the WBRT arm LEVEL 3.[19] In a European Organisation for Research and Treatment of Cancer trial of either resection or radiosurgery, with or without WBRT, adjuvant WBRT negatively impacted some aspects of health-related quality of life, although these effects were transitory. However, compliance with health-related quality of life was only 88.3% at baseline and dropped to an abysmal low of 45% at 1 year; in trials with such large components of missing data, imputing superiority is fraught with a lot of inherent biases LEVEL 1.[13] Recently, a larger intergroup trial in 213 patients with up to three brain metastases randomized patients to SRS or SRS plus WBRT. The primary endpoint was cognitive deterioration (decline of >1 standard deviation from baseline on at least 1 cognitive test at 3 mo), and secondary endpoints included the time of intracranial failure, quality of life, functional independence, long-term cognitive status, and overall survival. Patients randomized to SRS alone experienced less cognitive deterioration at 3 months, better quality of life at 3 months, and better overall quality of life; however, the time of intracranial failure was shorter without WBRT, and there were no significant differences in functional independence or overall survival between the treatment arms LEVEL 1.[20]

Therefore, the complete omission of WBRT must be approached cautiously, especially in the context of other reports in the literature, such as the oft-forgotten study by Pirzkall et al involving 236 patients, wherein SRS plus WBRT, compared to SRS alone (not a randomized trial), yielded better tumor control and reduced intracranial relapse and a trend toward improved survival, especially in patients with no extracranial disease (15.4 vs 8.3 mo, $P = .08$), underscoring the logical expectation that WBRT added to SRS improves brain disease control, and this has the potential to translate to a survival advantage, only in patients who are less likely to succumb to extracranial progression, once again underscoring the need to perform systemic disease restaging in trials attempting to define a survival difference. This finding was most recently supported by a secondary analysis of the Japanese trial of SRS versus SRS plus WBRT, in which patients with the best prognoses appeared to have a survival benefit from the addition of WBRT in reducing subsequent brain failures.

The American Society of Radiation Oncology, in 2014, recommended against routine use of WBRT in selected patients

with limited intracranial disease treated with SRS, but if these patients have limited extracranial disease, they may well be the exact group, which might actually experience a survival benefit with WBRT, analogous to the survival benefit that accrues to small cell lung cancer patients when WBRT is used to treat presumed intracranial microscopic disease in the context of well-controlled extracranial disease (the so-called PCI, although there is nothing truly "prophylactic" about this strategy, but in reality, it is therapeutic for micrometastatic intracranial disease). The advent of systemic therapies with better BBB penetration are truly needed before a complete shift to focal therapy alone can be safely performed.

It is important to understand that recurrence of cancer in any organ frequently leads to functional deterioration within that organ, and the brain should not be expected to be an exception to this; therefore, deferring WBRT or additional SRS until relapse may have potential detrimental neurocognitive and overall survival consequences because relapse in the brain may present with potentially devastating and irreversible symptoms. Very few studies carefully analyze the mode of death in brain metastasis patients. Regine et al, in a single institution experience, reported considerably increased intracranial relapses in patients treated with SRS alone but more importantly noticed that these were most often (71%) symptomatic and associated with a neurologic deficit. Patchell et al, in their seminal trial of resection +/− WBRT, tracked cause of death and identified neurologic death as occurring far more frequently in patients not receiving WBRT, a logical outcome of increased intracranial failure LEVEL 2.[21] One option to overcome this problem is frequent monitoring with screening MRI scans after initial SRS and salvage with repeat SRS at presymptomatic recurrence. However, such an option, even if it were shown to be effective in a randomized trial, would likely be associated with increased societal costs consequential to the intense MRI surveillance and salvage with repeat SRS, usually on more than one occasion. All of these factors must be weighed for each individual patient in order to optimize treatment.

Reirradiation

Despite good initial responses, most patients will eventually experience disease progression in the brain, and so the role of reirradiation must also be considered. SRS may be used to treat recurrence after WBRT and vice versa. In some cases, WBRT may be repeated and has been reported to improve symptoms in 40% to 70% of patients. To date, there is no randomized evidence regarding the role or reirradiation for brain metastases, and clinical decisions must be made on a case-by-case basis LEVEL 2.[22]

Chemotherapy, Targeted Therapy, and Immunotherapy

The role of chemotherapy, targeted therapy, or immunotherapy is not well defined but is evolving at a rapid pace. There is no level 1 evidence favoring the use of cytotoxic chemotherapy, and therefore, no standard chemotherapy is routinely used for the treatment of brain metastases, except perhaps for germinomas. In patients with brain metastases who have failed local therapy, the same chemotherapeutic agents employed for the treatment of extracranial disease are often used. Alternatively, drugs with good CNS penetration, such as temozolomide, topotecan, irinotecan, and high-dose methotrexate may be employed, even in patients in whom chemotherapy might have at most minor efficacy against the primary tumor.

Improved understanding of tumor biology has led to the identification of specific molecular drivers of cancer development and progression. Alterations involving the *EGFR* gene and *EML4–ALK* chromosomal translocation in lung cancer, human epidermal growth factor receptor 2 (HER2) protein overexpression in breast cancer, *BRAF* mutation in melanoma, and NTRK gene fusions in adult and pediatric solid tumors are examples of distinct subsets of cancer amenable to unique treatment approaches. There have been several prospective studies in the last 5 years particularly focusing on targeted therapies or immunotherapies, which have demonstrated promising outcomes.

Epidermal Growth Factor Receptor Inhibitors in Non–Small Cell Lung Cancer

The RTOG 0320 trial did not show any additional benefit of temozolomide or erlotinib when added to WBRT and SRS in unselected patients with NSCLC with one to three brain metastases LEVEL 2.[23] One of the limitations of this study was that patients were not stratified according to *EGFR* mutational status. In a phase II study of 40 NSCLC patients with brain metastases, WBRT and erlotinib was safe, and the median survival time was 11.8 months. In the 17 patients with known *EGFR* status, the benefit of erlotinib was more pronounced in the mutant *EGFR* patients (overall survival of 19.1 mo) as compared to the wild-type *EGFR* patients (overall survival of 9.3 mo). In a large cohort of 110 patients with *EGFR* mutant lung cancer with newly diagnosed brain metastases, patients treated with WBRT (32 patients) had longer median time to intracranial progression compared to 63 patients who received erlotinib therapy upfront (24 vs 16 mo). In a retrospective multiinstitutional analysis of 35 patients with *EGFR* mutated brain metastasis, the median survivals after SRS, WBRT, and EGFR inhibitor alone were 46, 20, and 25 months ($P < .001$), despite the most favorable patients being selected for systemic therapy alone. This study demonstrates that the deferral of RT and treatment with a systemic therapy alone that has modest efficacy, may result in a survival decrement, even in patients with these favorable mutational profiles (**Fig. 101.6**). In fact, these data lend further credence to the hypothesis that if a patient is destined to live longer than just a few months, intracranial control becomes a paramount goal, and using suboptimal approaches that raise the risk of intracranial relapse might risk a decrement in overall survival.

In a phase II study of gefitinib in 41 NSCLC patients unselected for *EGFR* mutation, an objective response rate of 10% in the brain was seen. Higher response rates were reported in studies of EGFR inhibitors in enriched with patients with known *EGFR* mutations. Third-generation EGFR inhibitors, such as osimertinib, are associated with higher response rates (50%-70%) and more durable disease control. Newer agents in the pipeline for patients with these mutations also include AZD-3759 and avitinib (against the EGFR T790M-resistant mutation).

Anaplastic Lymphoma Kinase Inhibitors in Non–Small Cell Lung Cancer

The first-generation ALK inhibitor crizotinib resulted in excellent extracranial disease control, however, poor (<20%) response rates in the brain due to limited BBB permeability. Next-generation novel ALK inhibitors, such as alectinib, ceritinib, and brigatinib, show better BBB penetration and intracranial disease control (>50%) in clinical studies. New molecular-based prognostic assessments also show longer survivals in these patients, due in significant part, to the increased efficacy of these next-generation agents.

FIGURE 101.6 Differential response to epidermal growth factor receptor inhibitors in brain metastasis. One patient with innumerable brain metastases **(A)** has an excellent response to treatment with targeted therapy alone **(B)**. Contrast this with another patient with the same epidermal growth factor receptor mutation only presenting with a single brain metastasis **(C)** who is treated with the same targeted therapy but experiences symptomatic progression of disease **(D)** necessitating salvage stereotactic radiosurgery.

Human Epidermal Growth Factor Receptor 2 Inhibitors for Breast Cancer

The prototypical, first-in-class HER2 inhibitor, trastuzumab, has extremely poor BBB penetration and was initially described as yielding responses in the context of leptomeningeal carcinomatosis from breast cancer but not for parenchymal disease. Several prospective clinical trials have evaluated the role of the second-generation agent, lapatinib, single, or in combination with fluorouracil therapy in *HER2*-positive breast cancer patients with active brain metastases. In one phase II study of lapatinib in patients with *HER2*-positive breast cancer with progressive brain metastases after WBRT and/or SRS, a true CNS response rate of only 6% was seen. In a single-arm phase II study, 29 of the 45 patients with newly diagnosed, previously untreated brain metastases from *HER2*-positive breast cancer achieved an objective CNS response (66%) with the combination of lapatinib and capecitabine LEVEL 1.[24] Similarly, neratinib and capecitabine have also demonstrated favorable response rates (49%) compared to neratinib alone (8%). Newer agents such as trastuzumab emtansine, tucatinib, and tesevatinib are also being evaluated in this subset of breast cancer patients. In this context, a nearly completed NRG Oncology trial (NCT01622868) is exploring combinatorial WBRT or SRS with lapatinib, based on limited preclinical data suggesting efficacy, and results are early awaited.

Inhibitors Targeting *BRAF* in Melanoma

Activating *BRAF* mutations that result in constitutive activation of the mitogen-activated protein kinase pathway affect approximately half of cutaneous melanoma patients, and more than 95% of these are the V600E mutations (substitution of valine by glutamic acid at the 600th amino acid position). In an open-label phase II study, 172 patients with V600E or V600K mutation–positive melanoma metastatic to the brain were treated with dabrafenib. Patients in cohort A had not received any prior local therapy, and cohort B had disease progression in the brain following local therapy (surgery, WBRT, SRS). Twenty-nine of 74 patients (39%) with V600E BRAF-mutant melanoma in cohort A and 20 of 65 (31%) patients in cohort B achieved an overall intracranial response. This study provided initial evidence that dabrafenib has activity in patients with V600E *BRAF*-mutant melanoma brain metastases irrespective of prior local therapy, but the response rates of 31% to 39% have to be considered modest at best, especially given that none of these were complete responses and durability was limited.

In a prospective study, 24 patients with V600E *BRAF* mutation–positive melanoma brain metastases were treated with vemurafenib. Of 19 patients with measurable intracranial disease, 7 (37%) achieved greater than 30% intracranial tumor regression, and 3 (16%) achieved a confirmed partial response, whereas 13 out of 21 patients (62%) had extracranial responses. A phase II study of vemurafenib in 146 patients with V600 *ERAF* mutation–positive melanoma brain metastases with or without prior treatment for their brain metastases yielded a best overall intracranial response rate of 18% in each cohort.

Combinatorial systemic therapy strategies are associated with higher response rates and more durable rates of disease control as observed in a multicenter, multicohort, open-label, phase II trial of dabrafenib and trametinib in patients with V600E *BRAF* mutation–positive melanoma brain metastases.

Inhibitors Targeting *NTRK*

NTRK gene fusions are present in a variety of adult and pediatric tumors and can be detected using a variety of assays, such as DNA sequencing, RNA sequencing, and plasma cell-free DNA profiling. Targeting this oncogenic driver mutation in select patients with first-generation NTRK inhibitors has been associated with incredible response rates (>75%) regardless of the primary tumor subtype. Recent studies have also demonstrated intracranial efficacy and durable disease control using selective NTRK inhibitors for patients with solid tumors with brain metastasis or primary CNS tumors harboring NTRK gene fusions. Ongoing clinical trials will further demonstrate intracranial efficacy in larger populations of patients.

Immune-Modulating Approaches

The development of immune-modulating agents, specifically immune checkpoint inhibitors, offers an exciting opportunity for treating patients with brain metastases. Recent research has demonstrated that activated T cells can be effective in brain metastases and other intracranial tumors. In a phase II study, 72 melanoma patients with brain metastases (51 asymptomatic [cohort A], 21 symptomatic and on steroids [cohort B]) were treated with ipilimumab, a monoclonal antibody against cytotoxic T-lymphocyte–associated protein 4. Twelve of 51 patients (24%) in cohort A and 2 of 21 patients (10%) in cohort B achieved CNS disease control. Median overall survival was 7.0 months in cohort A and 3.7 months in cohort B. This study demonstrated that ipilimumab could have some activity in recurrent brain metastases.

Recent trials using antibodies against the programmed cell death protein 1 receptor of lymphocytes for patients with brain metastases have also demonstrated modest intracranial efficacy with a variety of agents, alone, and in combinatorial approaches. For example, one phase II trial using pembrolizumab showed an intracranial response rate of 22% in melanoma brain metastasis and 33% in NSCLC brain metastasis. Combination strategies of ipilimumab and nivolumab have been demonstrated to result in response rates of approximately 50% in well-selected cohorts of patients. Exuberantly, enthusiastic commentators have prematurely suggested that these data are sufficient to replace radiotherapy in melanoma patients with brain metastases, but that is, in reality, far from the case, as these patients are extremely well-selected, and the majority of patients in clinical practice would not meet the eligibility criteria of these trials.

There is considerable interest in combining these immune checkpoint inhibitors with RT. A retrospective analysis of 13 patients treated with WBRT within 30 days of ipilimumab showed that 4 out of 9 patients (44 %) experienced a partial response or stable disease. In another retrospective review, the median survival of patients with melanoma with brain metastases treated with ipilimumab and brain SRS was comparable to patients without brain metastases. In a large cohort of patients with brain metastasis treated with SRS and anti–programmed cell death ligand 1 inhibitors, we recently showed that SRS and immediate immune checkpoint inhibition resulted in high rates of durable disease control without increased risk of treatment-related toxicity. Additional research is needed to clarify the role of combinatorial immunotherapy and radiotherapy.

FIGURE 101.7 Spinal cord compression from metastatic disease, sagittal, T2 magnetic resonance imaging.

EPIDURAL SPINAL COLUMN METASTASIS

Epidemiology and Clinical Manifestations

Metastatic disease to the spine can be LM (discussed in the following section) or intramedullary, but by far, the most common site is epidural. Epidural spinal metastases can cause severe neurologic compromise by compressing the thecal sac and ultimately the spinal cord. The cancers that most often are responsible for epidural metastatic disease to the spine include breast, prostate, and lung cancer. This is in part due to not only the relatively high incidence of these malignancies but also their predilection for metastatic disease spread to bones; the spinal column is the most common site of bone metastasis.

Epidural spinal cord compression can be a surgical emergency that occurs in up to 15% of patients with a history of cancer. This complication typically occurs in the setting of known bone metastases but, as with brain lesions, may be the presenting symptom for a new diagnosis of primary malignancy or for new diagnosis of metastatic disease. The most common level of cord compression is the thoracic level (59%-78%), followed by lumbar (16%-33%), and cervical (4%-15%) levels (Fig. 101.7). In up to 50% of patients, disease may involve multiple levels of the vertebral column. As with bone metastases, pain is the most common presenting symptom of spinal cord compression (96%). This may be not only from the bone itself but also from spinal cord or nerve root involvement. As compression worsens, patients may also develop other signs and symptoms of spinal cord compression including gait ataxia, focal weakness (76%-86%), sensory disturbances (51%-80%), and autonomic dysfunction (40%-64%). In most cases, epidural spinal cord compression occurs due to extension of disease from the bony vertebrae, but it sometimes may be due to infiltration of the neural foramina or paravertebral spaces or from a pathologic vertebral fracture. Compression of the spinal cord and blood vessels cause mechanical nerve damage and ultimately ischemia and infarction. The longer the cord is compromised, the more likely that the damage is irreversible; it is well established that long-standing, gradually worsening neurologic symptoms are unlikely to be markedly improved following therapeutic intervention due to the chronic nature of the damage.

Diagnosis

The diagnostic test of choice for spine metastasis of any kind is a contrast-enhanced MRI scan, but if the patient's condition is rapidly deteriorating, or if the patient is unable to tolerate the length of this study, a noncontrast MRI may be partially adequate. If, however, there is clinical suspicion for either intramedullary or leptomeningeal disease, then intravenous contrast is absolutely indicated. The entire spine should be studied in order to evaluate for multilevel involvement. Patients who are unable to undergo MRI should have a computed tomography myelogram.

Management

Initial palliation of pain from spinal metastasis is often with nonsteroidal anti-inflammatory drugs, narcotics, agents to ameliorate neuropathic pain, and corticosteroids.

For spinal cord compression, the goals of care are to preserve neurologic function and to relieve pain. The early recognition and initiation of treatment, even prior to definitive diagnosis,

are critical due to the time-sensitive chance of recovery from a neurologic deficit. As soon as clinical suspicion for cord compression is raised, treatment should begin with early administration of high-dose corticosteroids to decrease swelling because this has been shown to improve outcomes in acute spinal cord injury LEVEL 1.[25]

Surgery is the primary modality for relieving spinal cord compression, particularly in the setting of limited disease because it can result in immediate decompression. The seminal prospective study comparing the addition of surgery to RT in the setting of spinal cord compression showed not only improved neurologic and functional outcomes with surgery, including ambulation, continence, and decreased steroid and narcotic requirements but also an overall survival benefit (126 vs 100 d, $P = .033$) LEVEL 1.[26] Even in the absence of spinal cord compression, surgical management should be considered in the setting of an unknown primary malignancy or new metastatic disease in order to confirm the diagnoses. For patients with vertebral fracture or spinal instability, stabilization of the spine through surgical means should be considered. Anterior epidural metastases are more challenging to access and may require thoracotomy, whereas posterior lesions are likely to be amenable to laminectomy.

Given the grave consequences of progressive disease in the spine, RT, which is a highly effective palliative treatment with up to 90% of patients experiencing a significant reduction of pain, should be considered at an early stage. This is important because pain from a compression fracture and compressive symptoms from retropulsed bony fragments are almost never adequately relieved by any modality except surgery. RT can reduce the likelihood of a pathologic fracture, as may vertebroplasty. Should a fracture occur, surgical repair is the best option when possible, and postoperative RT is the standard of care. RT in this setting decreases the likelihood of local recurrence, which may compromise the integrity of the surgical repair/stabilization. The typical time frame is 1 to 2 weeks after surgery in order to allow for adequate wound healing. In selected patients, percutaneous vertebroplasty or kyphoplasty may be effective in relieving symptoms. None of these treatments will prolong survival but may have a significant positive impact on quality of life.

RT is also a common palliative treatment for epidural spinal cord metastases, particularly for cases in which surgery is not feasible (ie, multilevel cord involvement, multiple medical comorbidities) and in the postoperative setting. As with brain metastases, the effect from radiotherapy is gradual and lacks the immediate decompression of surgery. RT alone is therefore suboptimal in the setting of spinal cord compression. The classic regimen for palliative RT is 30 Gy in 10 fractions, but other shorter schedules can be used in patients with a poorer prognosis LEVEL 1.[27] For primary malignancies involving the bone, such as multiple myeloma or sarcoma, the prescribed dose may be lower or higher and the target volume more conservative to avoid overtreating neighboring structures, particularly the spinal cord.

RT may be contraindicated in patients who have received previous RT to the same site or for relatively radioresistant tumors such as renal cell carcinoma. Reirradiation may be considered using a highly focused, intensity-modulated technique because this has been shown to stabilize or improve neurologic status in the majority of patients with minimal risk of radiation myelopathy. Stereotactic body RT, highly focal fractionated radiation with sharp dose gradients similar to SRS, may also be employed in this setting in order to minimize unnecessary dose to the spinal cord. Sahgal et al report that normalized biologically effective doses less than a point maximum of 20 to 25 Gy carry a low risk for myelopathy so long because the total effective dose does not exceed approximately 70 Gy, and the stereotactic body RT maximum dose is less than half the total normalized dose. A prospective series of 59 patients from MD Anderson who underwent reirradiation of spinal metastases demonstrated 92% freedom from neurologic deterioration from any cause at 1 year. Multiple series have also demonstrated favorable outcomes for patients treated in the upfront setting with primary spine SRS. In a cohort of 500 cases treated with spine SRS, long-term pain improvement was observed in 86%, long-term tumor control in 90%, and 84% of patients with a progressive neurologic deficit prior to treatment experienced at least some clinical improvement. These clinical series support a completed but yet to be reported RTOG phase II/III trial, which explored SRS in the up-front treatment of spine metastases and will ultimately provide insight regarding the use of this approach LEVEL 2.[28] The phase II trial supported the feasibility of single-fraction SRS for spinal metastases with no serious treatment-related toxicities. The phase III component compares SRS versus classic fractionated external beam RT with regard to pain relief and quality of life. By far, the strongest prognostic factor for neurologic outcome is the patient's neurologic status prior to treatment. The best odds for regain of function are with surgery LEVEL 2.[26] With RT, 80% of ambulatory patients remained ambulatory, but only 50% of patients with paresis and less than 10% of those with paralysis will regain the ability to walk. Pain may be relieved in over 90% of patients treated with corticosteroids and RT. Overall survival is most strongly determined by systemic disease burden.

LEPTOMENINGEAL METASTASIS

Epidemiology and Clinical Presentation

LM refers to metastasis to the pia and arachnoid. The disease may be focal or disseminated, but any involvement of the meninges with cancer indicates that the entire CSF compartment is compromised. This devastating complication occurs in up to 5% to 10% of cancer patients, with acute lymphocytic leukemia and other hematologic malignancies representing the most common sources. The most common solid tumors that spread to the leptomeninges are breast cancer, NSCLC, melanoma, and gastrointestinal tract cancers. Surgical resection of brain lesions, particularly of the posterior fossa, has been reported as a risk factor for the development of LM. Most cases of LM are diagnosed in the setting of known metastatic disease, but LM may be an isolated phenomenon, particularly for hematologic cancers.

The median survival without treatment is 4 to 6 weeks. Appropriate treatment may prolong survival to several months, particularly for lymphoma, leukemia, and to a lesser extent breast cancer. Treatment may also potentially reverse or prevent further neurologic symptoms. The presence of systemic disease, obstruction of the CSF, gross CNS metastases, and poor performance status are negative prognostic factors.

Headache is a common presenting symptom (30%-50%), as are altered mental status and signs of focal neuropathy. Patients most commonly present with multifocal neurologic symptoms from spinal cord (60%), cerebral (50%), or cranial nerve

FIGURE 101.8 Leptomeningeal metastatic disease spread, axial T1 contrast-enhanced magnetic resonance imaging.

involvement (40%). Increased ICP or hydrocephalus may develop due to obstruction of CSF flow or from disruption of the BBB. Seizures occur in up to 25% of patients.

Diagnosis

In the workup of LM, MRI of the entire CNS should be performed. Even though the sensitivity and specificity of imaging are relatively low (76% and 77%), obvious LM on imaging obviates the need for CSF sampling by lumbar or other puncture. If LM is visualized, it appears as enhancement of the leptomeninges, cranial nerves, or nerve roots or as gross tumor nodules. Visible LM is most commonly seen at the base of brain, sylvian fissures, and cauda equina, perhaps due to slower CSF flow in these regions (Fig. 101.8).

LP should be performed for CSF analysis, particularly if the clinical suspicion for LM is high and MRI is negative. LP may show a combination of malignant cells, elevated opening pressure, low glucose, high protein, and leukocytosis, typically of lymphocytes. Assessing the CSF for tumor marker levels, although not standard, may aid in diagnosis. The false-negative rate for initial LP in the diagnosis of LM is relatively high at 50%, and therefore, this procedure may need to be repeated multiple times to increase diagnostic yield if clinically indicated. In as many as 20% of patients with clinical or radiographic LM, the CSF may be nondiagnostic despite multiple samples. LP is contraindicated if there is a risk for brain herniation and should therefore follow MRI to make this assessment.

Management

LM is generally an incurable condition with a poor prognosis, and a careful balance of risks and benefits of treatment approaches must be individualized. The focus of treatment is primarily palliation of symptoms. Treatment must address the entire CSF compartment, and therefore, focal therapy with surgery and/or RT has limited use. Nevertheless, neurosurgical evaluation should be considered for CSF shunting, typically to the peritoneum, or for placement of an intrathecal reservoir. CSF shunting carries a theoretical risk of spread of tumor cells into the destination space, but this risk is generally not clinically significant in the context of such limited survival.

Symptomatic or bulky focal lesions may be treated with RT in a similar fashion to epidural metastases. Craniospinal irradiation is not routinely indicated because it does not improve outcomes and can cause significant morbidity, especially in adults (nausea, dysphagia, fatigue, and myelosuppression).

ITC is the mainstay of treatment of LM because it allows circulation to the entire CSF volume; specific agents include methotrexate, cytarabine (in both standard and depot formulations), and thiotepa. Cytarabine, especially the depot form, should be preceded and followed by 2 to 3 days of corticosteroid prophylaxis because a severe chemical meningitis can otherwise result. Combination chemotherapy may be considered, although data showing increased efficacy are sparse. ITC is less effective in patients with obstruction of the CSF and contraindicated in the setting of increased ICP. Occasionally, a combination ventriculoperitoneal shunt/Ommaya reservoir device is implanted to both reduce ICP and serve as a method for ITC delivery; however, this requires careful coordination of valve positioning and all too often becomes obstructed with CSF cells. ITC is typically administered intraventricularly using an implanted Ommaya reservoir. Administration via LP is also possible, but this method is more cumbersome, painful, and less reliable. ITC carries a risk of meningitis, myelosuppression, and encephalopathy.

Disruption in the normal flow of CSF is a common phenomenon with LM. This has important implications in the administration of ITC because it can both decrease efficacy and increase toxicity. Assessment of the CSF flow with radionuclide cisternogram prior to ITC is beneficial but not universally available. MRI-based flow studies are emerging, but the level of resolution is limited in this context. Identification of sites of obstruction may allow focal treatment with RT prior to ITC, which may improve flow even in the absence of a discrete lesion. WBRT may be considered because it is well tolerated and may improve CSF flow.

Systemic chemotherapy has limited use in the treatment of LM due to the BBB, but this is an area of ongoing investigation. Additional palliative care with analgesics, corticosteroids, antiseizure medications, and CSF shunting should be initiated as indicated.

CONCLUSIONS

Metastatic disease to the CNS axis is a widespread and clinically important scenario. The diagnosis is generally made with a combination of history, physical exam, and imaging. In some cases, blood work, biopsy, or CSF sampling may also aid in diagnosis. Management of CNS metastases is accomplished with corticosteroids, surgery, radiotherapy, systemic therapy, or a combination of these modalities. The treatment plan and clinical outcome depend on the specific factors of that individual patient, including the location and extent of metastatic lesions, duration of symptoms, and the patient's ability to tolerate treatment.

Meningiomas 102

Thomas J. Kaley

KEY POINTS

1. Meningiomas are the most common primary brain tumor of adults and certainly the most common brain tumor most neurologists will encounter, as many are identified incidentally on imaging as computed tomography and magnetic resonance imaging are performed for many different indications.
2. The only clear risk factors for development of a meningioma are prior cranial radiation and the presence of a neurogenetic syndrome such as neurofibromatosis type 2. Meningiomas are more common in women than men, and incidence increases with advancing age.
3. Histologically, meningiomas are graded from the least aggressive World Health Organization grade I tumor to the most aggressive World Health Organization grade III tumor. The most common somatic alteration found on sequencing is an alteration leading to neurofibromatosis type 2 inactivation.
4. Typical diagnostic imaging findings are the presence of a homogenously enhancing extra-axial mass on computed tomography or magnetic resonance imaging with a characteristic dural tail.
5. Initial treatment options range from observation to surgery or radiation to combined surgery + radiation, depending on the meningioma grade, extent of resection, and clinical characteristics. Chemotherapy is usually reserved for surgery and radiation refractory meningiomas.

INTRODUCTION

Diseases of the dura are rather uncommon, except for meningiomas. Not just the most common dural disease, meningiomas are the most common intracranial primary tumor in adults. Especially in the current environment of neuroimaging with computed tomography (CT) or magnetic resonance imaging (MRI) being performed for any and every possible neurologic symptom, both symptomatic and more frequently asymptomatic meningiomas will be found. Accordingly, meningiomas will be the most common intracranial tumor neurologists, and most physicians, will encounter. Although many are benign, a meningioma may enlarge and/or cause neurologic dysfunction depending on its location within the brain. Because the cranium has only a limited capacity to accommodate an expanding mass, symptoms may occur. Surgery remains the treatment of choice, but not all meningiomas are amenable to complete resection, and some will recur and require further therapy. This chapter outlines the major dural diseases with the majority devoted to meningiomas.

MENINGIOMAS

Epidemiology

Meningiomas are the most common primary "brain" tumor in adults, although technically they are tumors of the brain covering rather than brain parenchyma. The Central Brain Tumor Registry of the United States estimates an incidence of approximately 20,000 new meningioma cases diagnosed per year. This represents 36% of all primary brain tumors. These tumors have a clear female predominance with an almost 2:1 female-to-male ratio. These tumors are quite rare in children except within a predisposing neurogenetic syndrome. They are substantially more common in adults and tend to increase in incidence with age, particularly older than the age of 65 years. Autopsy series suggest a meningioma prevalence of 2%, typically asymptomatic and discovered incidentally during life or postmortem.

The only clear risk factors for meningiomas are prior radiotherapy involving the head and neck region as well as predisposing neurogenetic syndromes, such as neurofibromatosis type 2. Ionizing radiation has also been demonstrated to be a clear risk factor for future meningioma development. Prior radiation therapy for an extracranial malignancy such as head and neck cancer or childhood leukemia is the most common. These meningiomas that develop as a result of prior radiotherapy tend to be more aggressive in their clinical course. The latency for meningioma development is inversely proportional to the dose of radiation delivered.

Although no longer performed, scalp radiation for tinea capitis, a fungal infection, has been linked to meningioma development. Similarly, older, less refined dental x-rays have been inconclusively linked to meningiomas. Currently however, radiotherapy is no longer performed for scalp infections and newer dental x-rays probably do not have significant risk, different from the older, less refined variant. Probably the most controversial potential link to meningiomas in the recent media and scientific literature has been the use of cellular phones. To date, there has been no proven definitive link between cellular phones and the development of a meningioma.

Pathobiology

Meningiomas are tumors that arise from the arachnoid coverings of the brain. Histologically, these tumors have various appearances depending on the subtype of meningioma, although most physicians frequently recall the whorling pattern of tumor cells, which is most common and calcium collections known as *psammoma bodies*. The World Health Organization (WHO) classifies meningiomas into three grades (**Table 102.1**).

The most common neurogenetic syndrome predisposing the patient to meningiomas is neurofibromatosis type 2, the less

TABLE 102.1 WHO Grading Criteria for Meningiomas

2007 WHO Criteria for Meningioma
WHO Grade I Meningioma
Angiomatous Fibrous Lymphoplasmacyte-rich Meningothelial Metaplastic Microcystic Psammomatous Secretory Transitional
WHO Grade II Meningioma
Clear cell Chordoid Atypical: ≥4 mitoses per 10 high-powered fields or at least three of the following features: • Increased cellularity • Small cells with a high nuclear to cytoplasmic ratio • Prominent nucleoli • Patternless or sheetlike growth • Necrosis
WHO Grade III Meningioma
Rhabdoid Papillary Anaplastic (malignant): ≥20 mitoses per 10 high-powered fields and/or malignant characteristics including: • Loss of typical growth patterns • Brain invasion • Abundant mitoses with atypical forms • Multifocal necrosis

Abbreviation: WHO, World Health Organization.

common form of neurofibromatosis. Neurofibromatosis type 2 is an autosomal dominant disorder with full penetrance caused by alteration of the *NF2* gene on chromosome 22, which encodes for the tumor suppressor protein Merlin (moesin-ezrin-radixin–like protein), also called *neurofibromin*. Approximately 80% of sporadic meningiomas also harbor *NF2* alterations. Some speculate that many of these are mosaics, and therefore, germline testing may be unrevealing, rather than true somatic genetic alterations. However, there is no clear selective therapy to target Merlin alterations.

Recent research efforts have focused on understanding the biology of cancer as a whole and utilizing targeted therapies that disrupt a specific biologic pathway, typically a growth factor ligand/receptor-mediated pathway. Meningiomas are highly vascular tumors with elevated expression of the vascular endothelial growth factor (VEGF) receptor and its ligand, VEGF. Other growth factor pathways such as platelet-derived growth factor, epidermal growth factor, insulin-like growth factor, and somatostatin are also expressed in meningiomas. Efforts at targeting these pathways are discussed in the chemotherapy section later in the text.

A major thrust of cancer investigation over the last decade has been whole genome sequencing to identify drugable oncogenic driver mutations. Mutations in two pathways recently were identified in approximately 20% of meningiomas: *AKT* and *SMO*. The *AKT* mutations disrupt the homeostasis that normally regulates cancer cell survival, proliferation, angiogenesis, and metabolism. The *SMO* mutations alter a key pathway responsible for controlling cancer cell self-renewal.

In the Clark et al's paper, genomic analysis revealed oncogenic mutations in *AKT1* and *SMO* in 13% and 4% of specimens, respectively. These mutated tumors tend to occur more frequently in skull base locations, which also tend to be the most surgically challenging or inaccessible areas. Patients with *AKT* mutations harbored the *E17K* mutation, a well characterized oncogenic mutation present in several other cancer types. The *E17K* mutation can be found in breast cancer, colorectal cancer, and lung cancer and results in constitutive AKT activation, which in turn stimulates downstream mammalian target of rapamycin activity, resulting in overactivity of the PI3K pathway. The PI3K pathway activation in turn stimulates multiple oncogenic processes including cell proliferation and angiogenesis. The *SMO* mutations included the L412F seen in a subset of medulloblastomas and the W535L alteration seen in basal cell carcinoma and predictive of sensitivity to U.S. Food and Drug Administration–approved therapy with vismodegib, a Hedgehog inhibitor. When the SMO protein is activated, it results in ligand-independent downstream activation of the Hedgehog pathway resulting in cell proliferation and cancer stem cell self-renewal.

In the Brastianos et al's paper, 65 meningioma specimens underwent analysis and revealed similar results identifying *AKT* and *SMO* mutations in a subset of patients. Five patients (8%) demonstrated *AKT* mutations, all E17K. Three patients (5%) demonstrated *SMO* mutations, two of which were the W535L mutation seen in basal cell carcinoma and one L412F alteration previously described in desmoplastic medulloblastoma. They then studied an additional 46 grade I tumors and 49 grade II and III tumors and found six AKT1 E17K mutated tumors (1 grade III, 5 grade I), and two SMO L412F mutated tumors (both grade I).

In summary, these two studies demonstrated that PI3K pathway activation and Hedgehog pathway activation occur in a subset of meningioma patients. The mutations seen are well characterized in other cancer types and in the case of basal cell cancer, predict therapeutic response to inhibition with an available agent. Future studies hope to define the role, if any, of these agents in the treatment of these particular molecular subtypes of meningioma. Most meningiomas that recur despite prior treatment with surgery and radiation do not harbor an *AKT* or *SMO* alteration, and the ultimate utility of finding these mutations is not yet known.

Clinical Manifestations

As with most other brain tumors, the clinical presentation of meningiomas is highly variable, depending on tumor location, size, and shape. Tumors may manifest as visual disturbances, speech dysfunction, weakness, sensory dysfunction, neurocognitive dysfunction, personality changes, or seizures. Because meningiomas are typically slow-growing neoplasms, they rarely cause acute increases in intracranial pressure resulting in symptoms like headache, nausea, vomiting, or alteration of consciousness. In fact, because they are such slow-growing tumors they can often become surprisingly large without causing any clinical neurologic dysfunction. However, even a "benign" meningioma can result in disabling neurologic dysfunction if it grows beyond the capacity of the skull to accommodate the increase in volume. Rarely, these tumors may metastasize outside the central nervous system, usually to bone. This is an exceptionally rare event, and typically only with malignant meningiomas.

Diagnosis

Meningiomas are best visualized on an MRI with contrast, which demonstrates a brightly enhancing mass arising off of the dura,

which typically has a linear continuation with the dura known as *a dural tail* (Fig. 102.1). A CT with contrast may demonstrate the same pattern of enhancement, but MRI provides a better visualization of the underlying brain. A CT may be superior for demonstrating any changes in the neighboring bone as meningiomas can trigger a reactive hyperostosis in the bone adjacent to the meningioma itself, seen in approximately 25% of patients. Without contrast, meningiomas appear on both CT and MRI as either hypo- or iso-dense/intense.

As with most tumors, neuroimaging alone cannot definitively diagnose a meningioma, which depends on tissue analysis acquired by biopsy or resection. The WHO classifies meningiomas in three grades (see Table 102.1). The WHO grade I meningiomas are classified as "benign" meningiomas and make up approximately 80% of meningiomas. They are typically slow-growing tumors that basically fail to demonstrate any of the characteristics of higher grade meningiomas. Grade I meningiomas include most of the histologic subtypes: angiomatous, fibrous, lymphoplasmacyte-rich, meningothelial, metaplastic, microcystic, psammomatous, secretory, and transitional meningiomas. The WHO grade II meningiomas include the clear cell and chordoid histologic variants as well as atypical tumors that harbor increased mitotic activity as evidenced by more than or equal to 4 mitoses per 10 high-powered fields, or at least three of the following features: increased cellularity, small cells with a high nuclear to cytoplasmic ratio, prominent nucleoli, patternless or sheetlike growth, or necrosis. Importantly, brain invasion is associated with increased rates of recurrence and is sufficient to diagnose a WHO grade II tumor regardless of the presence of other atypical features. The WHO grade III meningiomas include rhabdoid, papillary, and anaplastic (malignant). The criteria for anaplastic meningiomas include increased mitotic activity as evidenced by more than or equal to 20 mitoses per 10 high-powered fields and/or malignant characteristics resembling carcinoma, sarcoma, or melanoma, such as the loss of usual meningioma growth patterns, infiltration of underlying brain, abundant mitoses with atypical forms, and multifocal necrosis. Anaplasia is sufficient to diagnose a WHO grade III regardless of the presence of brain invasion.

Treatment

Despite advances in cancer therapy, the treatment of meningioma remains primarily surgical with the goal of maximum safe surgical resection. In patients in whom a meningioma is

FIGURE 102.1 Magnetic resonance imaging appearance of meningiomas including coronal T1 postcontrast image demonstrating a recurrent grade I meningioma **(A)**, coronal T1 postcontrast image demonstrating an atypical meningioma noting significant peritumoral edema **(B)**, axial T1 postcontrast image demonstrating an anaplastic meningioma noting brain invasion **(C)**, and sagittal T1 postcontrast image demonstrating extracranial growth of a recurrent surgery and radiation refractory meningioma **(D)**.

FIGURE 102.2 Algorithm for the treatment of meningiomas. Abbreviations: GTR, gross total resection; RT, radiation therapy; STR, subtotal resection.

unresectable due to location yet needs treatment, or in patients whose tumor is only amenable to a subtotal resection with persistent neurologic symptoms or dysfunction, radiation therapy is typically offered. Oftentimes, the biggest clinical question revolves around the timing of each of these therapies, which we discuss further within the individual grades of meningioma and is outlined in Figure 102.2.

Surgery

The goal of surgical resection is always maximum resection balanced against minimal neurologic surgical morbidity. The degree of surgical resection is graded on the Simpson grading scale, ranging from grade 1, which includes complete removal of not only the meningioma but also any involved dura or bone, through grade 5, which only includes decompression, with or without biopsy of the tumor. However, in clinical practice, the most commonly used terminology is *gross total resection* (removal of all visible tumor), *subtotal resection* (partial resection), or *biopsy* (only a small piece of tissue was removed for histologic diagnosis).

Radiotherapy

The two forms of radiotherapy used most often are external beam radiation therapy (EBRT) and stereotactic radiosurgery (SRS). An EBRT uses standard radiation techniques of delivering a lower dose of radiation per day over a longer course of treatment. The SRS delivers a very high dose of radiation, typically within one session. The SRS goes by many different names depending on the machine that is used, the energy source, and planning platform. The EBRT and SRS have never been compared against one another in a randomized prospective fashion. However, both EBRT and SRS of demonstrated efficacy in treating meningiomas in multiple retrospective series. Similarly, the different forms of SRS have never been compared against one another in a randomized fashion, but they are likely all comparable. The decision of whether to use EBRT or SRS is typically determined by the location of the tumor, potential complications of radiation, and expertise of the physician administering the treatment.

Chemotherapy

Unlike surgery and radiation, chemotherapy has yet to demonstrate a benefit in the treatment of meningioma. However, there is a need for effective medical or chemotherapy for certain subsets of patients with meningiomas, especially those with meningiomas refractory to surgery and radiation. In this subset, no medical therapy has yet proven effective. The other subset for which a viable chemotherapy approach is needed is patients in whom surgery and/or radiation is either technically not feasible due to tumor location or not advisable due to other circumstances.

Many chemotherapies have been studied in the treatment of meningioma; unfortunately no therapy has demonstrated clear efficacy in a randomized phase III trial (Table 102.2), and no U.S. Food and Drug Administration–approved therapies exist. Studies investigating traditional cytotoxic chemotherapies

TABLE 102.2 Medical Therapies Investigated for Meningioma

Drug	Mechanism of Action
Hydroxyurea	Ribonucleotide reductase inhibitor
Temozolomide	Alkylating chemotherapy
Irinotecan	Topoisomerase 1 inhibitor
Cyclophosphamide + Adriamycin + vincristine	Combination cytotoxic chemotherapy
Interferon-α	Immunomodulation
Mifepristone (RU486)	Antiprogesterone
Megestrol acetate	Progesterone receptor agonist
Medroxyprogesterone acetate	Synthetic progesterone
Tamoxifen	Antiestrogen
Octreotide	Somatostatin analogue
Sandostatin LAR	Somatostatin analogue
Pasireotide LAR (SOM230C)	Somatostatin analogue
Imatinib	PDGFR TKI
Erlotinib	EGFR TKI
Gefitinib	EGFR TKI
Vatalanib	VEGFR + PDGFR TKI
Sunitinib	VEGFR + PDGFR TKI
Bevacizumab	Anti-VEGF antibody
Everolimus	mTOR inhibitor
NovoTTF-100A (*external device*)	Microtubule inhibition
Pembrolizumab	Immunotherapy
Nivolumab	Immunotherapy
Abemaciclib	Cell cycle inhibitor (CDK inhibitor)

Abbreviations: CDK, cyclin-dependent kinase; EGFR, epidermal growth factor receptor; mTOR, mammalian target of rapamycin; PDGFR, platelet-derived growth factor receptor; TKI, tyrosine kinase inhibitor; VEGF, vascular endothelial growth factor; VEGFR, vascular endothelial growth factor receptor.

(temozolomide, hydroxyurea, irinotecan, and triple therapy with cyclophosphamide + doxorubicin + vincristine), hormonal therapies (progesterone and estrogen modulators), interferon α-2b, somatostatin analogues, and molecularly targeted therapies including inhibitors of platelet-derived growth factor (imatinib), epidermal growth factor receptor (gefitinib and erlotinib), have all been disappointing. The 6-month progression-free survival rates are less than 20%, similar to those for the most common and aggressive parenchymal brain tumor, glioblastomas.

Meningiomas are highly vascular, and targeting tumor vasculature may be a potentially effective strategy. Targeted therapy to disrupt tumor angiogenesis (the development of new blood vessels) such as VEGF receptor with the tyrosine kinase inhibitor sunitinib and targeting the VEGF ligand with the monoclonal antibody bevacizumab have shown some possible benefit and may represent a viable future treatment strategy. As such, both sunitinib and bevacizumab are included in the National Comprehensive Cancer Network guidelines for systemic therapy for recurrent meningiomas.

The recent discovery of oncogenic driver mutations in either AKT in the PI3K pathway or SMO in the Hedgehog pathway may provide potential therapeutic targets in a subset of patients. Inhibitors of AKT and SMO are currently in clinical trial development. However, *AKT* and *SMO* mutant tumors are a minority, and additional discoveries are desperately needed.

Outcomes

World Health Organization Grade I Meningioma

The preferred treatment of WHO grade I meningiomas remains surgical resection whenever feasible. With gross total resection, the 5-year recurrence rate is approximately 10% to 25%. With subtotal resection, it is approximately 25% to 50%. With either gross total resection or subtotal resection, postoperatively, these patients are managed with observation and surveillance imaging. Radiation is typically reserved for when patients have persistent neurologic dysfunction due to a tumor that cannot be completely resected or for patients who suffer a recurrence or progressive growth of their tumor.

World Health Organization Grade II Meningioma

As with grade 1 tumors, the initial and preferred management of WHO grade II meningiomas is also maximum safe surgical resection. If gross total resection is not achieved, absent an individual patient contraindication to radiotherapy. However, there is substantial controversy whether the benefits of immediate postoperative radiotherapy outweigh the risks for completely resected tumors. The 5-year recurrence rate after surgery alone is approximately 50%, and numerous retrospective series have demonstrated an increase in progression-free survival with the addition of postoperative radiotherapy, and some retrospective series have refuted this finding. In either body of literature, immediate postoperative radiotherapy (as opposed to radiotherapy at the time of recurrence) has yet to demonstrate an overall survival advantage and has risks. Fortunately, a large cooperative group randomized trial is ongoing, but results will take many years.

World Health Organization Grade III Meningioma

After surgery alone, the chance of recurrence at 5 years is 70% to 80% after gross total resection and 100% after subtotal resection. Therefore, postoperative radiation is nearly always offered to these patients in an attempt to increase the time before inevitable recurrence. Regardless, however, nearly all patients recur.

Incidental Meningioma

The incidental meningioma is a common yet often puzzling clinical situation. With imaging alone, there is uncertainty as to the histology, grade, and pace of growth (if any) of the incidentally found lesion. Often, the meningioma itself is asymptomatic and unrelated to the initial complaint that led to the neuroimaging. In the case of a small, asymptomatic incidentally found meningioma, the preferred treatment is one of observation. If repeat imaging demonstrates further stability then these tumors can be followed expectantly with periodic imaging and clinical evaluations. If there is growth, then typically a surgical intervention is offered to these patients.

OTHER DURAL DISEASES

Hemangiopericytomas

Hemangiopericytomas are tumors that also may arise off the dura and appear radiographically similar to meningiomas. However, they usually behave more like sarcomas with a more aggressive course, multiple recurrences, and metastases to extracranial organs (particularly bone, liver, and lung). Surgery and postoperative radiation are standard, although recurrence is nearly universal.

Dural Metastases

The radiographic appearance of metastases to the dura from extracranial malignancies (such as breast cancer) is usually very similar to that of meningiomas. However, dural metastases are more often multiple, may appear as diffuse dural thickening (below), and usually have a faster growth rate on subsequent images. These are more common in lymphoma and possibly breast cancer but should really be suspected in any patient with a systemic malignancy. The breast cancer patient is a particular challenge because these patients also have an increased incidence of meningioma. Short-interval imaging and reassessment can usually differentiate between dural metastasis and meningioma on the basis of the growth rate (faster with metastases, slower with benign meningiomas). Occasionally, these entities are mixed ("collision" tumor). Treatment is similar to metastatic disease elsewhere in the brain, considering radiation and chemotherapy, and occasionally surgery (especially if histology is in question). Dural metastases do differ from parenchymal metastases in that dural metastases are not protected by a blood-brain barrier–like parenchymal disease.

Hypertrophic Pachymeningitis

Hypertrophic pachymeningitis refers to a thickening of the dura, either focally or diffusely, that may be caused by a variety of different etiologies. In general, this is a rather rare disorder, although the differential is broad including infections (tuberculosis, fungal, syphilis), autoimmune (rheumatoid arthritis, Sjögren disease), vasculitic (Wegener, giant cell arteritis, Behçet disease), sarcoid, histiocytosis, and metastases from systemic malignancies as well as "idiopathic" hypertrophic pachymeningitis where no underlying etiology is identified.

The most common symptoms are headache, followed by visual dysfunction, then other cranial nerve dysfunction, and cerebellar dysfunction. Seizures may occur due to local irritation of underlying brain. Imaging features on MRI are typically diffuse dural enhancement, which may be either nodular or smooth. Evaluation for underlying causes should be sought, and lumbar puncture is typically necessary. In the idiopathic variety, there is typically a pleocytosis (usually lymphocytic) and elevated protein. Treatment is directed at the underlying cause or in the case of idiopathic hypertrophic pachymeningitis with immunosuppressive therapy, often starting with corticosteroids.

103 Primary Central Nervous System Lymphoma

Lakshmi Nayak and Tracy T. Batchelor

KEY POINTS

1. The majority of primary central nervous system lymphomas are diffuse large B-cell lymphoma.
2. Primary central nervous system lymphoma is characterized on magnetic resonance imaging by homogeneous contrast enhancement and restricted diffusion.
3. A comprehensive workup and extent of disease evaluation is essential to rule out systemic lymphoma.
4. Age and performance status are the most important prognostic factors independently associated with outcome.
5. High-dose methotrexate-based chemotherapy is the standard induction treatment for newly diagnosed primary central nervous system lymphoma.
6. Intensive chemotherapy followed by autologous stem cell transplant is considered in young and healthy patients for consolidation treatment of primary central nervous system lymphoma.
7. Relapse rate is high at 50% even in patients who had a good response to initial high-dose methotrexate-based chemotherapy.
8. There is a risk of delayed neurotoxicity with whole-brain radiation therapy particularly in combination with high-dose methotrexate.

INTRODUCTION

Primary central nervous system lymphoma (PCNSL) is a rare and aggressive extranodal non-Hodgkin lymphoma (NHL) confined to the brain, leptomeninges, eyes, or spinal cord. The prognosis of PCNSL is inferior to that of other extranodal NHL subtypes. The diagnosis and management of PCNSL differs from that of other primary brain cancers and systemic NHL.

EPIDEMIOLOGY

The PCNSL is an uncommon subtype of NHL. These tumors account for 2% of all primary brain tumors and approximately 4% to 6% of all extranodal lymphomas. An estimated 7,585 cases of PCNSL were diagnosed in the United States from 2011 to 2015, and the number of cases is expected to increase further with the aging of the US population. The median age at diagnosis is 66 years, and the disease is more common in men than women (ratio 1.22:1; $P < .001$). The incidence rate for PCNSL is 0.44 per 100,000 person-years. Congenital or acquired immunodeficiency is the only established risk factor for PCNSL and individuals infected with the human immunodeficiency virus (HIV) are at greater risk for developing this tumor. However, the incidence of HIV-related PCNSL has declined significantly over time, and this chapter focuses on PCNSL in the immunocompetent host.

PATHOBIOLOGY

More than 90% of PCNSL cases are diffuse large B-cell lymphomas (DLBCL), with the remainder consisting of T-cell lymphomas, poorly characterized low-grade lymphomas, or Burkitt lymphomas. Primary central nervous system (CNS) DLBCL is composed of highly proliferative malignant tumor cells clustered in the perivascular space, with reactive lymphocytes, macrophages, and activated microglial cells intermixed with the tumor cells. Most tumors express pan–B-cell markers including CD19, CD20, CD22, and CD79a. The molecular mechanisms underlying transformation and localization to the CNS are poorly understood. Limitations in molecular studies of PCNSL include the rarity of the disease and the limited availability of tissue because the diagnosis is most often made with stereotactic needle biopsy. Like systemic DLBCL, PCNSL harbors chromosomal translocations of the *BCL6* gene, deletions in 6q, and aberrant somatic hypermutation in protooncogenes including *MYC* and *PAX5*. Inactivation of *CDKN2A* is also commonly observed in both entities. The DLBCL can be classified into three molecular subclasses by gene expression profiling: germinal center B-cell–like (GCB), activated B-cell–like (ABC), and type 3 subgroup. The non-GCB or ABC subtype is associated with an inferior prognosis versus the GCB profile. Nearly all cases of primary CNS DLBCL most closely resembles the ABC cell of origin subtype. This higher prevalence of the ABC cell of origin subtype in PCNSL may partially account for the relatively inferior prognosis of this lymphoma versus other forms of extranodal DLBCL. Moreover, recent comprehensive genomic studies have indicated certain molecular features distinguish primary CNS DLBCL from systemic DLBCL. The PCNSL exhibits B-cell receptor signaling pathway activation concurrently with toll-like receptor signaling, which is affected by recurrent *MYD88* and *CD79B* mutations. In one study, 9p24.1/*PDL1*/*PDL2* copy number gains were observed, whereas in another study, copy number gains of 9p24.1/*PDL1*/*PDL2* were not observed. The PCNSL is characterized by differential expression of genes related to adhesion and the extracellular matrix pathways, including *MUM1*, *CXCL13*, and *CHI3L1*. The ongoing somatic hypermutation with biased use of V_H gene segments that has been observed in PCNSL is suggestive of an antigen-dependent proliferation. These observations are consistent with the hypothesis that PCNSL is secondary to antigen-dependent activation of

circulating B cells, which subsequently localize to the CNS by expression of various adhesion and extracellular matrix–related genes. However, further molecular studies to investigate the transforming events and the subsequent events responsible for CNS tropism in PCNSL are needed. Insights into the molecular pathogenesis of PCNSL has led to the development of targeted therapeutic approaches for this tumor.

CLINICAL FEATURES AND DIAGNOSIS

The presenting symptoms and signs of PCNSL are variable and often depend on the location of CNS involvement. In 248 immunocompetent patients with PCNSL, 70% had focal neurologic deficits, 43% had neuropsychiatric signs, 33% had symptoms of increased intracranial pressure, 14% had seizures, and 4% had ocular symptoms. Seizures are less common than with other types of brain tumors probably because PCNSL involves predominantly subcortical white matter rather than epileptogenic gray matter. Unlike patients with systemic NHL, PCNSL patients rarely manifest B symptoms. Imaging typically demonstrates a single, homogenously enhancing lesion and less commonly multifocal enhancing brain lesions. Concurrent cerebrospinal fluid (CSF) and eye involvement can occur in up to 20% of cases. Intramedullary spinal cord lesions are rare.

The International PCNSL Collaborative Group (IPCG) has developed guidelines to determine extent of disease. A gadolinium-enhanced brain magnetic resonance imaging scan is the most sensitive radiographic study for the detection of PCNSL. The characteristic appearance of PCNSL on magnetic resonance imaging is a homogeneous contrast-enhancing lesion with perilesional T2 signal change typically related to vasogenic edema (**Fig. 103.1**). Restricted diffusion on diffusion-weighted imaging is often seen due to high cellularity and high nuclear to cytoplasmic ratio of tightly compacted malignant cells. These radiographic features may help differentiating PCNSL from other malignant tumors, inflammatory, infectious, or demyelinating conditions. Rarely, nonenhancing lesions are seen. The definitive diagnosis of PCNSL is typically made by stereotactic brain biopsy, CSF analysis, or analysis of vitreous aspirate in patients with ocular involvement. Given the possible delay in diagnosis and treatment with the latter two methods, prompt stereotactic biopsy is advised in almost all cases that are surgically accessible. A thorough diagnostic evaluation is needed to establish the extent of the lymphoma and to confirm localization to the CNS. Physical examination should consist of a lymph node examination, a testicular examination in men, and a comprehensive neurologic examination. A lumbar puncture should be performed if not contraindicated, and CSF should be assessed by flow cytometry, cytology, and immunoglobulin heavy-chain gene rearrangement. Involvement of the optic nerve, retina, or vitreous humor should be excluded with a comprehensive eye evaluation by an ophthalmologist that includes a slit lamp examination. Blood tests should include a complete blood count, a basic metabolic panel, serum lactate dehydrogenase, and HIV serology.

Because extraneural disease must be excluded to establish a diagnosis of PCNSL, computed tomography or computed tomography/positron emission tomography scans of the chest, abdomen, and pelvis and a bone marrow biopsy and aspirate should be performed to exclude occult systemic disease. Testicular ultrasound is recommended in older men to rule out primary testicular lymphoma, which has a predilection for the brain.

TREATMENT

Newly Diagnosed Primary Central Nervous System Lymphoma

Treatment for newly diagnosed PCNSL consists of induction and consolidation phases. Typically, induction consists of chemotherapy with the objective of achieving a response/remission. Once this response/remission is achieved, a different chemotherapy regimen or whole brain radiation therapy (WBRT) is administered to "consolidate" the response/remission or reduce the risk of recurrence. Defining response to treatment in PCNSL requires assessment of all sites (brain, CSF, eye) potentially involved by disease. The IPCG has established response

FIGURE 103.1 Magnetic resonance images from a patient with primary central nervous system lymphoma. **A:** A T1-weighted, axial, postcontrast scan demonstrates intense, homogenous enhancement of the tumor in the corpus callosum. **B:** An axial T2/fluid-attenuated inversion recovery scan at the same anatomic level demonstrates hyperintense signal surrounding the tumor, reflecting vasogenic cerebral edema.

TABLE 103.1 International Primary Central Nervous System Lymphoma Collaborative Group Consensus Guidelines for the Assessment of Response in Primary Central Nervous System Lymphoma

Response	Brain Imaging	Steroid Dose	Ophthalmologic Examination	CSF Cytology
Complete response	No contrast-enhancing disease	None	Normal	Negative
Unconfirmed complete response	No contrast-enhancing disease	Any	Normal	Negative
	Minimal enhancing disease	Any	Minor RPE abnormality	Negative
Partial response	50% decrease in enhancement[a]	NA	Normal or minor RPE abnormality	Negative
	No contrast-enhancing disease	NA	Decrease in vitreous cells or retinal infiltrate	Persistent or suspicious
Progressive disease	25% increase in enhancing disease	NA	Recurrent or new disease	Recurrent or positive
	Any new site of disease[a]			
Stable disease	All scenarios not covered by responses above			

Abbreviations: CSF, cerebrospinal fluid; NA, not applicable; RPE, retinal pigment epithelium.
[a]Based on longest single dimension of lesion.

criteria that have been adopted into most prospective clinical trials of PCNSL. Because PCNSL is a multicompartmental disease potentially involving the brain, eye, and CSF, these response criteria include assessment of each of these components (Table 103.1).

Corticosteroids decrease tumor-associated, vasogenic edema and may result in partial radiographic regression of PCNSL. An initial response to corticosteroids is associated with a favorable outcome in PCNSL. However, after an initial response to corticosteroids, almost all patients quickly progress. Corticosteroids should be avoided, if possible, prior to a biopsy, given the risk of disrupting cellular morphology, resulting in a nondiagnostic pathologic specimen.

Surgical resection is not considered part of the standard treatment approach for PCNSL given the deep, infiltrative, and multifocal nature of this tumor. Accordingly, the role of neurosurgery in PCNSL is generally to establish a diagnosis via stereotactic biopsy. Cytoreductive surgery can be considered as a lifesaving intervention in extreme cases with large lesions and impending herniation. Historic studies demonstrated that surgical resection did not add benefit to survival and in fact led to worsened outcomes due to complications from surgery. More recent studies have indicated potential survival benefit in patients undergoing surgical resection; however, these are retrospective in nature. Given that PCNSL is chemosensitive, surgical resection is to be avoided, although biopsies obtaining larger tissue samples may be considered for comprehensive genomic analysis.

Historically, PCNSL was treated with WBRT at doses ranging from 36 to 45 Gy, which resulted in a high proportion of radiographic responses but also early relapse. In a multicenter phase 2 trial, 41 patients were treated with WBRT to 40 Gy plus a 20-Gy tumor boost and achieved a median overall survival (OS) of 12 months. Given the lack of durable responses to radiation and the risk of neurotoxicity associated with this modality of therapy, WBRT alone is no longer a recommended treatment for most patients with newly diagnosed PCNSL. Moreover, because PCNSL is an infiltrative, multifocal disease, focal radiation or radiosurgery is not recommended.

An effective treatment for PCNSL is intravenous, high-dose methotrexate (HD-MTX) at variable doses (1-8 g/m^2), typically used in combination with other chemotherapeutic agents and/or WBRT. However, there is no consensus on the optimal dose of HD-MTX. Doses of methotrexate 3 g/m^2 or higher result in therapeutic concentrations in the brain parenchyma and CSF. It is now widely recognized that there is a high incidence of neurotoxicity in patients older than the age of 60 years treated with combined modality treatment that includes WBRT. This observation prompted studies using *lower doses* of WBRT. In a multicenter phase 2 study, no significant neurocognitive decline on formal neuropsychiatric testing was observed after consolidative reduced-dose WBRT (23.4 Gy) and cytarabine (AraC) in patients who had achieved a complete response to induction chemotherapy including HD-MTX. Further study and longer neuropsychological follow-up of these patients is necessary to definitively assess the safety of this regimen because numerous studies have demonstrated the delayed neurotoxic effects of WBRT in the PCNSL population.

Given the risk of clinical neurotoxicity, other studies have assessed whether WBRT can be *eliminated* from the initial management of PCNSL. In a multicenter phase 3 trial, patients were randomized to receive HD-MTX–based chemotherapy with or without WBRT LEVEL 1.[1] Five hundred fifty-one patients were enrolled, of whom 318 were treated per protocol. Intent to treat analysis revealed that patients treated in the combined modality arm (chemotherapy + WBRT) achieved improved progression-free survival (PFS), but there was no improvement in OS, demonstrating that the elimination of WBRT from the treatment regimen did not appear to compromise OS. This has led to deferral of WBRT and the application of chemotherapy-alone approaches for newly diagnosed PCNSL patients. These approaches are based on a foundation of HD-MTX. Variable doses and schedules of HD-MTX have been used, but in general, a dose of 3 g/m^2 or higher delivered as an initial bolus followed by an infusion over 3 hours administered every 10 to 21 days is recommended for optimal outcomes and adequate CSF concentrations. Multiple phase 2 studies have demonstrated the safety, efficacy, and relatively preserved cognition of HD-MTX–based chemotherapy regimens. Moreover, longer duration of induction chemotherapy with HD-MTX (more than six cycles) results in higher complete response proportions.

It has now been shown in multiple single-arm as well as randomized trials that addition of other chemotherapeutic agents to HD-MTX results in improved responses. In a phase 2 trial, 79 PCNSL patients were randomized to receive either HD-MTX *versus* HD-MTX + AraC LEVEL 1.[2] All patients underwent consolidative WBRT after induction chemotherapy. The HD-MTX + AraC arm had a higher proportion of complete radiographic responses (CR) and a superior 3-year OS.

Rituximab, a chimeric monoclonal antibody targeting the CD20 antigen on B lymphocytes, has improved survival in other forms of extranodal NHL. However, rituximab has poor penetration of the blood brain barrier. When rituximab is administered intravenously at doses of 375 to 800 mg/m^2, CSF levels from 0.1% to 4.4% of serum levels are achieved. Despite limited CSF penetration, radiographic responses were reported in relapsed PCNSL patients treated with rituximab monotherapy, and this antibody has been incorporated into contemporary regimens for PCNSL. In historical retrospective comparisons, the CR are higher with induction regimens that include rituximab versus those in which there is no rituximab. The IELSG32, a randomized phase 2 trial assessed the efficacy of addition of rituximab with or without thiotepa to HD-MTX and AraC combination. In this trial, sequential addition of rituximab (CR 30%, hazard ratio [HR] 0.74) and thiotepa (CR 49%, HR 0.46) demonstrated improved response rates compared to HD-MTX and AraC (CR 23%) LEVEL 2.[3] Conversely, in an open-label, randomized, phase 3 trial of 200 patients to assess the role of rituximab in induction chemotherapy, a benefit in the primary end point, event-free survival, was not observed. In this study, event-free survival at 1 year was 49% versus 52%, respectively, in the rituximab-containing versus no rituximab groups (HR 1.00, $P = 0.99$) LEVEL 1.[4] Given the conflicting results regarding the role of rituximab in these two randomized trials, the role of this agent in the management of newly diagnosed PCNSL is uncertain.

In the preceding studies, WBRT was employed in the consolidation phase of treatment. However, other approaches have eliminated WBRT in the treatment of newly diagnosed PCNSL. In a multicenter, phase 2 study, 44 PCNSL patients were treated with induction chemotherapy consisting of HD-MTX, rituximab, and temozolomide, all drugs with demonstrated efficacy as monotherapy in PCNSL. This induction chemotherapy was followed by consolidation chemotherapy consisting of intravenous etoposide and AraC. Sixty-six percent of these patients achieved CR; median PFS of the entire group was 2.4 years, and median OS was not reached at the time of publication. These results are comparable to regimens that include WBRT. It is noteworthy that PFS was shorter in PCNSL patients in whom chemotherapy was delayed longer than 1 month after diagnosis compared to those patients who promptly initiated chemotherapy (3-year PFS of 20% vs. 59%, $P = .05$). This observation highlights the importance of early diagnosis and prompt initiation of chemotherapy in PCNSL patients.

Given the limited durability of responses observed in many studies of PCNSL, there is interest in high-dose chemotherapy (HDT) followed by autologous stem cell transplantation (ASCT) as consolidative therapy with curative intent for newly diagnosed PCNSL. Conditioning regimens including thiotepa have demonstrated encouraging results. In a multicenter phase 2 study, 79 patients were treated with induction HD-MTX, AraC, rituximab, and thiotepa, followed by carmustine and thiotepa conditioning prior to ASCT. The overall radiographic response (ORR) was 91%, 2-year OS was 87%, and treatment-related deaths occurred in less than 10% of enrolled patients. The toxicities, mostly cytopenias, were manageable.

Encouraging results from HDT and ASCT in uncontrolled studies has led to the development of randomized studies comparing this approach as an alternative to WBRT for consolidation. The second component of the IELSG32 study evaluated 2-year PFS in patients who achieved stable disease or better and were subsequently randomized to either WBRT or ASCT. Either consolidative approach was effective in both groups; with PFS2 of 69% in the group receiving ASCT and 80% in WBRT (HR 1.50, $P = 0.17$) LEVEL 1.[5] Importantly, both strategies were well tolerated with a 3% transplant-related mortality rate. Neurocognitive function progressively improved in patients who underwent ASCT within the first 2 years of follow up, but in those who received WBRT, there was a decline in attention and executive function. In another prospective, randomized phase 2 trial, the PRECIS study, patients received induction chemotherapy with two cycles of rituximab, HD-MTX, carmustine, etoposide, prednisone (R-MBVP) and then two cycles of rituximab, AraC (R-AraC) and were then randomly assigned to receive either consolidative WBRT versus ASCT with thiotepa-busulfan-cyclophosphamide conditioning LEVEL 2.[6] Although the study was designed as a noncomparative study and both arms met predetermined efficacy thresholds, the 2-year PFS favored the ASCT arm at 87% versus 63% in the WBRT group. This study demonstrated similar neurocognitive outcomes to IELSG32, favorable for the ASCT arm. However, 11% of patients died from ASCT-related toxicity.

A next generation of randomized trials have eliminated WBRT from the consolidation and are assessing HDT/ASCT versus nonmyeloablative chemotherapy regimens (NCT01511562, NCT02531841).

Several first-generation chemotherapy regimens for PCNSL included intrathecal chemotherapy. However, a number of nonrandomized studies that included intrathecal chemotherapy did not improve outcomes in PCNSL relative to regimens that did not include intrathecal injections of chemotherapy. Moreover, the ability to consistently achieve micromolar concentrations of methotrexate in the CSF at a dose of 8 g/m^2 as well as added toxicity from intrathecal chemotherapy has led to the elimination of this approach from most of the induction chemotherapy regimens currently in use.

Treatment of Primary Central Nervous System Lymphoma in Elderly Patients

Elderly patients account for more than half of all the subjects diagnosed with PCNSL. Older age is an adverse prognostic factor, and the risk of neurotoxicity is highest in this population. In general, chemotherapy alone is the preferred option for this subgroup. The majority of PCNSL patients older than 60 years of age develop clinical neurotoxicity after treatment with a WBRT-containing regimen, and some of these patients die of treatment-related complications rather than recurrent disease. Several studies have indicated that HD-MTX at doses of 3.5 to 8 g/m^2 is well tolerated in elderly patients who have adequate renal function with manageable grade 3 or 4 renal and hematologic toxicities. In a multicenter, randomized, phase 2 trial of chemotherapy alone in elderly patients with PCNSL, 98 patients were randomized to receive three cycles of either MPV-A (HD-MTX, procarbazine, vincristine, AraC) or a more simplified, potentially less toxic regimen consisting of MT

(HD-MTX and temozolomide) LEVEL 2.[7] Although trends favored the MPV-A regimen over the MT regimen with respect to CR, PFS, and OS, none of these differences reached statistical difference. Subsequent studies suggest that the addition of rituximab to both MPV and MT could increase the radiographic response rate. The PRIMAIN multicenter study investigated the use of rituximab, HD-MTX, procarbazine, and lomustine (R-MPL) in patients 65 years of age or older. Lomustine was omitted over the course of the study due to toxicities. The 2-year PFS and OS were 37.3% and 47%, respectively. Although there was no randomization of patients to R-MPL versus R-MP (rituximab, HD-MTX, procarbazine) given lomustine was dropped during the study, R-MP was found to be more feasible and as efficacious in this patient population. Moreover, a meta-analysis of 783 elderly patients (pooled data from clinical trials and nontrial patients) showed that HD-MTX–based treatment was associated with improved survival, and there was no difference in outcomes regardless of whether oral alkylating chemotherapy or aggressive chemotherapy was added to HD-MTX. Any of the above chemotherapy regimens are reasonable options in elderly PCNSL patients.

Relapsed and Refractory Primary Central Nervous System Lymphoma

Despite high initial response rates with HD-MTX–based induction therapy, most patients with PCNSL experience relapse. Moreover, approximately 20% to 30% of newly diagnosed PCNSL patients have HD-MTX–refractory disease. The majority of relapses occur within the first 2 years from initial diagnosis, although late relapses also occur. Prognosis of relapsed or refractory PCNSL is poor with a limited number of prospective phase 2 studies and no randomized studies for guidance on management. Rechallenge with HD-MTX is effective in patients who had previously responded to this agent. In a multicenter retrospective study of 22 relapsed PCNSL patients with a history of prior response to HD-MTX, 91% had a radiographic response to the first salvage treatment with HD-MTX and 100% to second salvage. The median OS from the first salvage was 61.9 months. In patients who have not previously been treated with HDT/ASCT, this is also an option at the time of relapse. In a phase 2 trial of 43 patients with relapsed or refractory PCNSL, salvage therapy with high-dose AraC and etoposide was followed by HDT/ASCT with a conditioning regimen consisting of thiotepa, busulfan, and cyclophosphamide. Twenty-seven patients ultimately proceeded to transplantation. Twenty-six of 27 patients had a CR, and the median PFS and OS in this group were 41.1 and 58.6 months, respectively. It is noteworthy that in a small series of patients with relapsed PCNSL after initial HDT/ASCT, a second autotransplantation was successful as salvage treatment. Finally, WBRT in relapsed patients who have not received it as a part of their initial treatment can be an effective option in this setting, although the risk of neurotoxicity remains a concern. In a series of 27 relapsed or refractory PCNSL patients treated with WBRT (median dose 36 Gy), 74% achieved an ORR and the median OS was 10.6 months. Delayed neurotoxicity rates of 15% were noted at doses greater than 36 Gy even in the setting of short survival. Other agents such as temozolomide, rituximab, pemetrexed, and topotecan have been studied in the context of retrospective and prospective studies with variable ORR and poor durability typically under 6 months. Targeted agents based on the unique mutations, alterations, and dysregulated signaling pathways active in PCNSL have been studied. A multicenter phase 2 study of temsirolimus, an inhibitor of mammalian target of rapamycin, demonstrated an ORR of 54%, although median PFS was 2.1 months. Immunomodulatory drugs such as lenalidomide and pomalidomide have been studied in phase 1 dose-escalation studies in recurrent and refractory PCNSL with ORR 48% to 64% and median PFS of ≤6 months. The REVRI study, which was a multicenter phase 2 study including induction treatment with eight cycles of rituximab and lenalidomide, followed by a maintenance program of 12 monthly cycles of lenalidomide monotherapy, met its primary end point of 32% ORR at the end of induction with a median PFS of 7.8 months. Ibrutinib, which is a Bruton tyrosine kinase inhibitor, was investigated in three phase 1 studies in doses of 560 and 840 mg, by itself or in combination with other chemotherapeutic agents including HD-MTX. These studies demonstrated adequate CSF drug concentrations at higher doses with ORR of 72% to 89%. A multicenter phase 2 study of single-agent ibrutinib at 560 mg demonstrated ORR of 52% and median PFS of 4.8 months. Based on these studies, lenalidomide and ibrutinib are now included in the National Comprehensive Cancer Network guidelines as potential options for PCNSL. Checkpoint inhibitors and chimeric antigen receptor T cells are also being studied in pilot, phase 1, and phase 2 studies.

Neurotoxicity

The most frequent complication in long-term PCNSL survivors is delayed neurotoxicity. Although this risk is significant, the exact incidence of delayed neurotoxicity is unclear, as most prior studies did not systematically assess neurocognitive function with serial neuropsychological testing. The elderly patients are at highest risk for this complication, with nearly all patients older than the age of 60 years developing clinical neurotoxicity following combined modality therapy (HD-MTX and WBRT). Treatment with WBRT has been identified as the major risk factor for the development of late neurotoxicity. Common symptoms and signs include deficits in attention, memory, executive function, ataxia, and incontinence. These deficits can have a detrimental impact on quality of life. Radiographic findings include periventricular white matter changes, ventricular enlargement, and cortical atrophy (**Fig. 103.2**). Pathologic studies of patients with delayed neurotoxicity reveal demyelination, hippocampal neuronal loss, and large-vessel atherosclerosis. Although the pathophysiology is unclear and likely multifactorial, damage to neural progenitor cells has been implicated to play an important role in radiation-related neurotoxicity. Currently, there are no treatments to reverse these delayed neurotoxic effects. Neuropsychological function was maintained in one long-term follow-up study of PCNSL patients treated with chemotherapy alone. The IELSG32 and PRECIS studies that compared WBRT to HDT/ASCT indicated that neurocognitive function improved in patients on the transplant arms and deteriorated with time in the WBRT groups. It is critical that serial neuropsychological assessments are incorporated into the management of patients with PCNSL, as cognitive outcome is a critical end point. The IPCG has developed an instrument for this purpose, which is composed of quality-of-life questionnaires and standardized neuropsychological tests that include assessment of executive function, attention, memory, and psychomotor speed, the cognitive domains most sensitive to this treatment-related effect.

FIGURE 103.2 Magnetic resonance image from a patient with delayed neurotoxicity from high-dose methotrexate-based chemotherapy and whole brain radiation. An axial T2 fluid-attenuated inversion recovery scan shows periventricular white matter changes and atrophy.

OUTCOME

Two prognostic scoring systems have been developed specifically for PCNSL. In a retrospective review of 105 PCNSL patients, the International Extranodal Lymphoma Study Group (IELSG) identified age older than 60 years, Eastern Cooperative Oncology Group performance status greater than 1, elevated serum lactate dehydrogenase level, elevated CSF protein concentration, and involvement of deep regions of the brain as independent predictors of poor prognosis. In patients with zero or one factor, two or three factors, or four or five factors, the 2-year survival proportions were 80%, 48%, and 15%, respectively. In another prognostic model, PCNSL patients were divided into three groups based on age and performance status: (1) younger than 50 years old, (2) 50 years or older with a Karnofsky performance status greater than or equal to 70, and (3) 50 years or older with a Karnofsky performance status less than 70. Based on these three divisions, significant differences in overall and failure-free survival were observed. There is no "staging" system that correlates with prognosis or response to treatment in PCNSL.

As our insight into the biology of PCNSL increases and treatment improves, more patients are living longer, emphasizing the need to optimize neurocognitive function and quality of life. The IPCG recommends a schedule of follow-up neuroimaging studies and cognitive assessment in PCNSL survivors (Table 103.2).

TABLE 103.2 Recommended Follow-up Assessments for Primary Central Nervous System Lymphoma

Follow-up Schedule	Assessments	Additional Optional Assessments
Years 1-2, every 3 mo	History and physical examination Cognitive testing (MMSE) Brain MRI CSF studies and ophthalmologic evaluation if positive at baseline (until negative)	IPCG cognitive battery test at baseline and every 6 mo
Years 3-5, every 6 mo	History and physical examination Cognitive testing (MMSE) Brain MRI	IPCG cognitive battery
Years 6-10, every 12 mo	History and physical examination Cognitive testing (MMSE) Brain MRI	IPCG cognitive battery

Abbreviations: CSF, cerebrospinal fluid; IPCG, International Primary CNS Lymphoma Collaborative Group; MMSE, mini-mental status examination; MRI, magnetic resonance imaging.

Tumors of the Pituitary Gland 104

Pamela U. Freda, John Ausiello, and Jeffrey N. Bruce

KEY POINTS

1. Pituitary tumors are common, benign neoplasms.
2. Most pituitary tumors present because of signs or symptoms of hormone excess or deficiency or visual disturbance due to compression of the optic chiasm.
3. All suspected pituitary adenomas require a complete endocrinologic evaluation for pituitary and target gland hormone excess or deficiency.
4. Transsphenoidal pituitary surgery using microscopic or endoscopic technique is the initial treatment of choice for hormonally inactive pituitary tumors that produce signs of mass effect, are in close proximity to the optic chiasm or exhibit significant growth, and for most endocrine-secreting tumors except prolactin-secreting tumors.
5. For tumors not cured surgically, medical therapies can be used to control excess hormone secretion and radiation therapy or radiosurgery is typically effective at controlling tumor growth.

INTRODUCTION

Pituitary tumors are a common medical problem often found incidentally on routine magnetic resonance imaging (MRI) scans. These tumors are overwhelmingly benign but may cause symptoms due to mass effect, compression of the optic chiasm, excess hormonal secretion, or hypopituitarism. As such, the diagnosis and management of these tumors involves the coordinated efforts of neurosurgeons, endocrinologists, and ophthalmologists.

EPIDEMIOLOGY

The true prevalence of pituitary adenomas is difficult to ascertain because most are asymptomatic; autopsy estimates of prevalence range from 1.7% to 24%. No sexual predilection exists, but the tumors are most common in adults, peaking in the third and fourth decades. Children and adolescents account for approximately 10% of cases. Pituitary tumors are not hereditary except for rare families with multiple endocrine neoplasia I (MEN-I), an autosomal dominant condition manifested by a high incidence of pituitary adenomas and tumors of other endocrine glands.

PATHOBIOLOGY

Pituitary tumors can be classified in four ways: by size, endocrine function, clinical findings, or histology. The first two remain the most common, as the majority of tumors are histologically benign and the clinical findings usually reflect the size or hormonal function of the tumor. With regard to size, microadenomas are less than 1 cm in diameter and macroadenomas are greater than 1 cm. Typically, when microadenomas cause symptoms, it is due to excess hormone secretion, whereas with macroadenomas, it is via compression of normal glandular or neural structures. Macroadenomas may invade the dura or bone and may infiltrate surrounding structures such as the cavernous sinus, cranial nerves, blood vessels, sphenoid bone, and brain. These locally invasive pituitary adenomas are nearly always histologically benign. In some studies, the proliferation index correlates with growth velocity and recurrence. However, their invasive character may be independent of their growth rate.

Tumors can be classified by the presence (or absence) of endocrine function, dividing tumors into secreting or nonsecreting tumors. Secreting tumors produce one or more anterior pituitary hormones, including prolactin (the most common), growth hormone, adrenocorticotropic hormone (ACTH) (causing Cushing disease), follicle-stimulating hormone, or luteinizing hormone. Mixed secretory tumors account for 10% of adenomas; interestingly, these adenomas still have a monoclonal origin. Secretion of more than one hormone has implications for medical therapy, as all excess hormone secretion must be treated. Nonfunctioning tumors do not secrete biologically active hormones or demonstrate clinical evidence of hormone excess. Immunohistochemistry for anterior lobe hormones and lineage-specific transcription factors allow for accurate cell lineage–based classification of resected tumor tissue.

In general, adenomas grow more slowly in older patients than younger patients. *Pituitary carcinomas* are rare but highly invasive, rapidly growing, and anaplastic. Unequivocal diagnosis relies on the presence of distant metastases, as certain histologic findings including pleomorphism and mitotic figures may be seen in benign adenomas.

The posterior pituitary, which contains the terminal processes of hypothalamic neurons and supporting glial cells, is a rare site of neoplasia. *Infundibulomas* are rare tumors of the neurohypophysis that are variants of pilocytic astrocytomas. *Granular cell tumors* (eg, *myoblastomas* or *choristomas*) are rare tumors of the neurohypophysis of uncertain origin.

CLINICAL MANIFESTATIONS

Clinical manifestations arise either from endocrine dysfunction or mass effect with invasion or compression of surrounding neural and vascular structures. The manifestations and management of hormonally active tumors are discussed in Chapter 122. Here, discussion is primarily limited to nonsecretory tumors, most of which are macroadenomas by the time they come to clinical attention. Macroadenomas may present with panhypopituitarism if the normal pituitary gland is destroyed. Headaches result from stretching of the diaphragma sellae and adjacent dural structures

FIGURE 104.1 Pituitary macroadenoma. Bitemporal hemianopia; visual acuity *right eye* 15/200, *left eye* 15/30. The blind half-fields are black. (Courtesy of Dr. Max Chamlin.)

that transmit sensation through the first branch of the trigeminal nerve. Visual field abnormalities are caused by compression of the crossing fibers in the optic chiasm, first affecting the superior temporal quadrants and then the inferior temporal quadrants, leading to a bitemporal hemianopia. Further expansion compromises the noncrossing fibers, first affecting the lower nasal quadrants followed by the upper nasal quadrants (Fig. 104.1).

Visual loss may be accompanied by optic disc pallor and loss of central visual acuity, although papilledema is rare. Patients usually complain of blurring or dimming of vision but often are unaware of peripheral visual loss. Formal visual field testing is important because some tumors affect only the macular fibers, causing central hemianopic scotomas that may be missed on routine screening. Bitemporal hemianopia is most common, but any pattern of visual loss is possible, including unilateral or homonymous hemianopia.

Lateral extension of the tumor with compression or invasion of the cavernous sinus may compromise third, fourth, or sixth cranial nerve functions, manifesting as diplopia. The third cranial nerve is most commonly affected. Numbness may occur in the V1 or V2 distribution. Overall, however, cranial nerve dysfunction is not a common feature of adenomas and may be more suggestive of other neoplasms of the cavernous sinus.

Adenomas can become quite large before causing symptoms. Suprasellar extension may compress the foramen of Monro, causing hydrocephalus and symptoms of increased intracranial pressure. Hypothalamic dysfunction can lead to diabetes insipidus, but this condition is relatively rare. If diabetes insipidus is present, it is more suggestive of inflammation or possible tumor invasion of the pituitary stalk. Extensive subfrontal extension with compression of both frontal lobes may cause personality changes or dementia. There may be seizures or motor and sensory dysfunction. Erosion of the skull base is a risk factor for the development of cerebrospinal fluid (CSF) rhinorrhea.

In about 5% of pituitary tumors, the first symptoms are those of pituitary apoplexy caused by hemorrhage or infarction of the adenoma. Symptoms include sudden onset of severe headache, oculomotor palsies, nausea, vomiting, altered mental state, diplopia, and rapidly progressive visual loss. Apoplexy is diagnosed by computed tomography or MRI and occasionally is an indication for emergency surgery (Fig. 104.2). Histologically, the adenoma shows massive necrosis and hemorrhage. Apoplexy is almost always caused by a pituitary tumor, but it has been reported in other conditions, such as lymphocytic hypophysitis. Pituitary adenomas may enlarge during pregnancy, causing acute symptoms or even apoplexy.

DIAGNOSIS

An algorithm for the initial assessment of a pituitary mass is shown in Figure 104.3. Despite the lack of level 1 evidence, endocrine and ophthalmologic evaluations are recommended in the workup of pituitary masses.

Radiographic Features

An MRI is the best way to evaluate pituitary pathology because soft tissue is seen clearly without interference from the bony surroundings of the sella. An MRI also produces images in any plane, which helps define the relationship of the tumor to the surrounding structures. Vascular structures including the adjacent carotid artery are easily visualized by signal void. Normally, the anterior lobe of the pituitary gland has the same signal as white matter on T1-weighted imaging. With gadolinium, the normal gland enhances homogeneously. Small punctate areas of heterogeneity may be the result of local variations in vascularity, microcyst formation, or granularity within the gland. The posterior lobe shows increased signal on T1-weighted images, probably representing neurosecretory granules in the antidiuretic hormone–containing axons.

Microadenomas are sometimes difficult to see directly on MRI but may be inferred by glandular asymmetry, focal sellar erosion, asymmetric convexity of the upper margin of the gland, or displacement of the infundibulum (Fig. 104.4).

The normal gland usually shows more enhancement than a microadenoma (Fig. 104.5). In the presence of a macroadenoma, the normal gland may not be visualized and the bright signal of the posterior lobe may be absent. Areas of increased signal on the T1-weighted image may stem from hemorrhage; areas of low signal may represent cystic degeneration. An MRI alone is usually sufficient, but computed tomography may show the bony anatomy in better detail. An MRI typically excludes an aneurysm, but magnetic resonance angiography or an angiogram is indicated if aneurysm is a serious diagnostic concern.

Among the group of functional adenomas, ACTH-secreting tumors are often too small to visualize on MRI. Therefore, the diagnosis requires the presence of clinical features typical of

FIGURE 104.2 Pituitary apoplexy. T1-weighted sagittal (A) and coronal magnetic resonance imaging (MRI) (B) demonstrating a pituitary mass that turned out to be partially hemorrhagic in a patient with apoplexy. Hyperintensity *(arrows)* corresponds to the hemorrhagic component. C: Postoperative sagittal MRI following successful tumor resection through a standard transsphenoidal approach shows cerebrospinal fluid within the enlarged sella *(arrow)*. D: Coronal MRI shows normal gland *(arrow)* along the floor of the sella with no residual tumor.

[a]Initial tests include prolactin, TSH, FT4, LH/FSH, E2, testosterone, ACTH, cortisol, GH, and IGF-1. Additional tests including dynamic studies may be needed to assess functional status.

FIGURE 104.3 Initial assessment of pituitary tumors. Abbreviations: ACTH, adrenocorticotropic hormone; E2, estradiol; FSH, follicle-stimulating hormone; FT4, free thyroxine; GH, growth hormone; IGF-1, insulin-like growth factor 1; LH, luteinizing hormone; MRI, magnetic resonance imaging; TSH, thyroid-stimulating hormone.

Cushing disease coupled with biochemical evidence of excess cortisol secretion. Typically, patients will have elevated 24-hour urinary free-cortisol levels, loss of ACTH suppression by high-dose as opposed to low-dose glucocorticoids, and elevated serum ACTH levels. However, the specific differentiation of an ACTH-secreting pituitary tumor from ectopic sources of ACTH may require measurement of ACTH peripherally and in each inferior petrosal sinus, which drains the pituitary gland.

Endocrine Evaluation

Complete endocrine evaluation is necessary for all patients with pituitary tumors, not only to establish the diagnosis of a secreting adenoma but also to determine the presence of hypopituitarism (Tables 104.1 and 104.2), which may result from compression of the normal pituitary gland.

Serum hormone levels should be obtained in all patients, and adequate hormone replacement should be administered for any deficiencies identified. Long-term follow-up monitoring is essential because hypopituitarism may develop years after diagnosis and treatment. Nonsecreting tumors may cause slight

FIGURE 104.4 Pituitary microadenoma. A: T1-weighted coronal magnetic resonance imaging shows slight tilting of the pituitary stalk to the left *(arrow)*, with questionable fullness of the right pituitary gland. These are secondary signs of pituitary microadenoma but are not sufficient to establish the diagnosis radiographically. B: T1-weighted coronal scan after gadolinium enhancement demonstrates a tiny focus of relative hypointensity within the right pituitary gland *(arrow)* consistent with a microadenoma. (Courtesy of Dr. S. Chan.)

elevations of serum prolactin levels (typically <104 ng/mL) via compression of the pituitary stalk leading to interruption of dopaminergic fibers that inhibit prolactin release. Mild elevations are common and must be distinguished from prolactin-secreting macroadenomas that are more likely when prolactin levels are greater than 200 ng/mL. This distinction is important therapeutically because nonsecreting tumors do not respond to dopamine agonists (eg, cabergoline or bromocriptine).

FIGURE 104.5 Pituitary adenoma. T1-weighted coronal magnetic resonance imaging after gadolinium enhancement demonstrates a discrete focus of hypointensity *(arrow)* in the right pituitary gland, most consistent with pituitary adenoma. (Courtesy of Dr. S. Chan.)

Differential Diagnosis

Most lesions in the differential diagnosis have characteristic radiographic or clinical syndromes that distinguish them from pituitary adenomas. Craniopharyngiomas have a predilection for children, are calcified, and usually include cystic areas that contain highly proteinaceous fluid with cholesterol crystals. Rathke cleft cysts are similar to craniopharyngiomas but have a cystic appearance without any solid component. Meningiomas are commonly

found in the diaphragma sellae, planum sphenoidale, and tuberculum sellae and may be difficult to distinguish from a macroadenoma. Distinguishing characteristics of meningiomas include enhancement, visualization of a cleavage plane between the mass and the sellar contents, normally sized sella, and the presence of a dural tail of enhancement. Optic glioma, hypothalamic glioma, germinoma, dermoid tumor, metastasis, and nasopharyngeal carcinoma are less commonly seen entities that should be considered. Chordomas characteristically show extensive bony destruction of the clivus. Mucoceles of the sphenoid sinus may simulate pituitary adenoma. Visual symptoms and sellar enlargement may also result from chronic, increased intracranial pressure of any origin. Characteristic signal voids on MRI usually distinguish an aneurysm. The differential diagnosis also includes sarcoidosis, lymphoma, lymphocytic hypophysitis, and other granulomatous diseases.

Herniation of the subarachnoid space into the sella through an incompetent diaphragma sellae may produce the empty sella syndrome, with enlargement of the sella and flattening of the pituitary gland on its floor (**Fig. 104.6**). This syndrome may be associated with pseudotumor cerebri or CSF rhinorrhea. Although most are not symptomatic, an empty sella may be associated with headaches and occasionally with mild hypopituitarism, but the visual fields are usually normal. The condition is readily seen on MRI and may be a complication of previous transsphenoidal surgery.

MANAGEMENT

Pituitary tumors are histologically benign tumors but can be associated with a significant decrease in a patient's quality of life and functional capacity. Early intervention may minimize disability and must address both hormonal and neurologic function.

Treatment of pituitary adenomas begins with replacement of any deficient pituitary hormone; replacement of thyroid and adrenal hormones remains the most important. Steroid replacement must be adequate for stressful situations, including surgery on the pituitary lesion. Typically, in patients with normal adrenal function prior to surgery, dexamethasone 4 mg is administered preoperatively and tapered off by postoperative day 2 (in patients requiring a craniotomy, the starting dose may be dexamethasone 10 mg perioperatively with a more prolonged taper). A morning cortisol level can be evaluated prior to discharge. Patients with known secondary adrenal insufficiency preoperatively should be continued on replacement doses after surgery.

The goals of treatment differ according to the functional activity of the tumor. For endocrinologically active tumors, an aggressive approach aimed at reversing hypersecretion while

FIGURE 104.6 Empty sella. **A:** Sagittal T1-weighted magnetic resonance imaging demonstrates low-intensity intrasellar signal *(long arrow)* representing cerebrospinal fluid (compare with same signal within the fourth ventricle—*short arrow*). **B:** Coronal T2-weighted magnetic resonance imaging increased signal within the sella *(black arrow)* representing cerebrospinal fluid and normal optic chiasm *(white arrow)*. (Courtesy of Dr. Alex Khandji.)

FIGURE 104.7 Prolactinoma. **A:** T2-weighted coronal magnetic resonance imaging of a 19-year-old man with a markedly elevated serum prolactin level. The tumor is partially compressing the optic chiasm *(arrow)*. **B:** Coronal magnetic resonance imaging after treatment with a dopamine agonist shows marked decrease in the tumor size such that the infundibulum *(black arrow)* and optic chiasm *(white arrow)* are decompressed.

preserving normal pituitary function is essential. This may often be achieved by surgical excision, although prolactinomas are generally better controlled by giving dopamine agonists, such as cabergoline. These medications cause tumor shrinkage and normalization of prolactin levels in almost all microadenomas and a majority of macroadenomas (Fig. 104.7). In a subset of patients with hormonally active tumors refractory to standard therapy (typically ACTH secreting), chemotherapy has been used, but further discussion of this treatment modality is beyond the scope of this chapter.

Candidates for surgical treatment also include patients with prolactinomas who fail to respond medically or those who do not tolerate the side effects of medication. The treatment strategies for secretory adenomas are covered in detail in Chapter 122.

Nonsecreting tumors are best treated by surgical reduction of the mass while maintaining pituitary function. Surgery offers the best chance for cure while providing a pathologic diagnosis of the tumor. Incidentally discovered asymptomatic adenomas require no intervention but should be followed with periodic visual field examination and MRI. Onset of symptoms or MRI documentation of growth is an indication for treatment.

Surgery

Although no level I evidence exists, the efficacy and safety of the transsphenoidal approach makes it the procedure of choice for the removal of adenomas. Both microscopic and endoscopic approaches seem to produce equivalent results. Most tumors are soft and friable; transsphenoidal access, although limited, permits complete removal even if there is suprasellar extension or the sella is not enlarged. Transsphenoidal surgery was originally developed by Cushing, but refinements in microsurgery and the availability of steroid replacement and antibiotics have dramatically improved the results.

A transcranial approach may be preferred for resection of exceptionally large tumors or those extending into the middle fossa or the suprasellar space through an intact diaphragma sellae with a waistband constriction of the tumor (Fig. 104.8). A transcranial approach may be necessary to decompress the optic structures before radiation when a transsphenoidal approach fails to adequately debulk the tumor or there is persistent major visual loss.

Radiation Therapy

Radiation therapy is complimentary to surgery in preventing progression, recurrence, and treating hormonally active tumors refractory to medical therapy. Standard radiation now uses conformal treatment planning to avoid unnecessary dosage to the temporal lobes. Doses of 4,500 to 5,000 cGy, delivered in 180 cGy fractions, are recommended. Radiation may be the only treatment for patients who are poor operative risks but in whom histologic confirmation is desired. Radiation therapy is usually not the initial treatment for hormonally active tumors because full normalization of hormone levels often does not occur for years afterwards.

Radiation therapy is indicated for patients with recurrent, medically refractory, hypersecreting tumors or administered postoperatively to patients with invasive or large, incompletely removed adenomas. It is not routinely administered after gross total resection; these patients are followed with serial MRI and visual field examination, and radiation is reserved for documented tumor regrowth.

Early complications of radiation therapy are transient and involve minor inconveniences such as epilation, dry mouth,

FIGURE 104.8 Giant pituitary adenoma. **A:** T1-weighted coronal magnetic resonance imaging with gadolinium showing a contrast-enhancing giant pituitary adenoma reaching up to the floor of the third ventricle with extension laterally to the right *(arrow)*. A large tumor such as this often requires a craniotomy to decompress the optic structures adequately. **B:** Coronal magnetic resonance imaging after a gross total resection of the pituitary adenoma through a craniotomy. There is no residual tumor, and the optic chiasm and a portion of the infundibulum may be seen clearly *(arrow)*.

and altered taste or smell. The most common and important delayed complication is hypopituitarism, which may occur any time from 6 months to 10 years after treatment. Annual endocrine evaluation is necessary to monitor for this complication. Other rare complications include visual loss, radiation necrosis of the temporal lobes, and radiation-induced tumors. To minimize risk of visual loss, optic structures should be decompressed before radiation therapy.

Newer techniques, such as radiosurgery using proton beam, Gamma Knife, or the linear accelerator, are effective for select patients. In these methods, a single high-dose fraction is directed to a limited volume, giving a high biologic effect. These methods may produce more rapid clinical and hormonal responses, potentially with less toxicity. However, there is concern about damage to the optic chiasm or cranial nerves. Radiosurgery is not used for large tumors or those less than 3 mm distance from the optic apparatus. This therapy may also be associated with a higher incidence of hypopituitarism.

Recurrent Tumors

Patients with recurrent tumors are difficult to manage, and treatment must be individualized. If the patient has not had prior radiation, then it would be the treatment of choice. Otherwise, repeat transsphenoidal surgery is usually indicated. Other treatment options include stereotactic radiosurgery, which may be effective and safe even in the patient who has had standard external beam radiotherapy.

OUTCOME

Given the diverse clinical spectrum seen with pituitary masses, outcomes are variable and dependent on the size and characteristics of the tumor, the therapeutic modality being assessed, and the preexisting comorbidities of the patient at the time of diagnosis.

Surgery

Transsphenoidal surgery is safe with mortality rates less than 1% and major morbidity rates less than 3.5%. Morbidity includes stroke, visual loss, meningitis, CSF leak, cranial nerve palsy, and diabetes insipidus, which is often transient.

Assessing long-term clinical outcomes in patients with nonsecreting adenomas is challenging due to the scarcity of definitive data. Total resection at time of surgery is dependent on the size of tumor and the experience of the surgeon; in selected centers, it may be as high as 75%. Rates of recurrence vary from different surgical series but have been estimated to be 20%. They are dependent on a host of clinical and nonclinical factors including tumor size, presence of symptoms on presentation, nature of the tumor (solid vs cystic), and the skill of the surgeon. The presence of a residual adenoma on postoperative MRI has been shown to correlate with increased risk of recurrence. Some improvement in visual function is estimated to occur in 80% of patients. Restoration of normal endocrine function is dependent on preoperative status in addition to the aforementioned factors. Patients with preexisting hormonal deficiencies typically will not have restoration of full pituitary function.

Regarding functional tumors, outcomes are dependent on tumor type and a full discussion is beyond the scope of this chapter. For patients with Cushing's disease and acromegaly, cure is possible if the tumor is small and symptoms are mild on presentation but risk of recurrent or residual disease increases with larger tumors or more advanced symptoms at time of diagnosis.

Radiation Therapy

Radiation therapy is highly effective in controlling tumor growth (80% or higher depending on length of follow-up). Stereotactic radiosurgery may be more effective in patients who are candidates for this modality. Some degree of hypopituitarism occurs in 30% to 50% of patients across all radiation modalities.

Medical Therapy

Dopamine agonists (cabergoline is most commonly used with starting dose of 0.25 mg once or twice a week that may be titrated based on prolactin levels and radiographic response) are highly effective in treating prolactinomas and reducing prolactin levels and tumor size in more than 90% of patients. Tumor size does impact outcomes, as macroprolactinomas have lower response rates than microprolactinomas but nonetheless, a majority will still respond to dopamine agonists.

Pineal Region Tumors 105

Jeffrey N. Bruce

KEY POINTS

1. Because of the wide histologic diversity, tissue diagnosis via surgical biopsy is essential to guide optimal management strategies.
2. If β-human chorionic gonadotropin (β-hCG) or α-fetoprotein levels are elevated, malignant germ cell elements must be present, so treatment with radiation and chemotherapy can commence without biopsy.
3. If only β-hCG is elevated (>50 IU/L) but α-fetoprotein is normal, patients should undergo surgery to distinguish a β-hCG–secreting germinoma from an immature teratoma or a choriocarcinoma, as the latter ones need more aggressive treatment.
4. Most patients present with increased intracranial pressure from obstructive hydrocephalus and usually benefit from an endoscopic third ventriculostomy.
5. Complete tumor resection is the surgical goal for benign and low-grade tumors in the pineal region. Most malignant tumors benefit from maximal safe tumor resection, but gross total resection is not recommended for localized germinomas as they are sensitive to radiation treatment.
6. Patients with malignant pineal tumors require adjuvant radiation therapy. Adjuvant chemotherapy is useful for nongerminomatous malignant germ cell tumors.
7. Patients with pineal cell or germ cell tumors require magnetic resonance imaging of the complete spine to look for spinal seeding.

INTRODUCTION

The pineal gland is composed of glandular tissue, glia, endothelial cells, and sympathetic nerve terminals. The numerous cell types that make up the normal gland and surrounding periventricular region may lead to a diverse group of tumors ranging from benign to malignant (Table 105.1), all of which may have a similar clinical presentation. Despite the common presentation, the specific histology has important implications for treatment and outcome. Optimal management of pineal region tumors therefore necessitates establishment of an accurate histologic diagnosis.

EPIDEMIOLOGY

Pineal tumors account for about 1% of all intracranial tumors in the United States. In Asia, where germ cell tumors (GCTs) are common, pineal cell tumors constitute 4% to 7% of all intracranial tumors. The GCTs are found almost exclusively during the first three decades of life, whereas pineal cell tumors have a mean age of diagnosis around 30 years of age. Although intracranial GCTs are overwhelmingly more common in men, there seems to be no strong gender preference among other pineal tumor types.

TABLE 105.1 Summary of Pathologically Verified Pineal Tumors at the New York Neurological Institute (1990-2013)

Type	Benign	Malignant	Male-to-Female Ratio	Average Age (y)
Germ cell	3	29	15:1	22
Pineal cell	16	29	1:1	41
Glial cell	18	20	1:1.5	38
Meningioma	9	2	1:2.7	46
Pineal cyst	14	0	1:2.5	36
Miscellaneous (including metastases)	3	15	1:1	40
Total	63	95	1.1:1	36

PATHOBIOLOGY

The pineal gland is an encapsulated structure situated between the velum interpositum of the posterior and the tectum of the midbrain. The gland produces melatonin in response to light-dark cycles and may play an ill-defined role in circadian rhythms. Pineocytomas and pineoblastomas arise from pineal glandular elements, astrocytomas and oligodendrogliomas from glial cells, hemangioblastomas from endothelial cells, and chemodectomas from sympathetic nerve cells. Arachnoid cells in the reflections of the tela choroidea, adjacent to the pineal gland, give rise to meningiomas. Ependymomas arise from ependymal cells that line the third ventricle. The GCTs derive from primitive germ cell rests that are retained in the pineal and other midline structures after embryologic migration.

Histologic Subtypes

Germ Cell Tumors

The GCTs account for approximately one-third of all pineal tumors and are histologically identical to gonadal GCTs. They predominate in men and usually occur in children and adolescents. Pineal GCTs occur almost exclusively in boys, but suprasellar tumors occur equally in boys and girls. The GCTs fall into two major categories: germinomas and nongerminomatous (NGGCT)

TABLE 105.2 Immunohistochemical Markers in Germ Cell Tumors[a]

Tumors	AFP	β-hCG	CD30	CD117	D-240	Glypican 3	OCT4	SOX2
Immature teratoma	+/−	−	−	−	−	+/−	−	+
Pure germinoma	−	−	−	+	+	−	+	−
Germinoma with syncytiotrophoblastic cells	−	+	−	+	+	−	+	−
Embryonal cell carcinoma	−	+/−	+	−	−	−	+	+
Choriocarcinoma	−	+	−	−	−	+	−	−
Endodermal sinus tumor (yolk sac tumor)	+	−	−	−	−	+	−	−

Abbreviations: AFP, α-fetoprotein; β-hCG, β-human chorionic gonadotropin; OCT4, octamer-binding transcription factor 4; SOX2, SRY (sex determining region Y)-box 2.
[a]Courtesy of George Zanazzi, MD.

that include choriocarcinomas, embryonal cell carcinomas, teratomas (mature and immature teratoma, teratoma with malignant transformation), and endodermal sinus tumors (also known as *yolk sac tumor*). Benign, mature teratomas may also be seen.

Germinomas arise in the midline, usually in the pineal area and suprasellar cistern and occasionally in both areas simultaneously. Rarely do they develop in the cerebral hemispheres. Germinomas account for about half of all intracranial GCTs. They are histologically identical to the testicular seminoma and ovarian dysgerminoma. Germinomas are highly malignant; pathologically, they are frequently infiltrated by lymphocytes, which may occasionally confuse the diagnosis. Pure germinomas generally are associated with absent α-fetoprotein (AFP) and β-human chorionic gonadotropin (β-hCG) levels in both cerebrospinal fluid (CSF) and serum; however, some may contain syncytiotrophoblastic elements that produce β-hCG, which confers a slightly worse prognosis in some studies (Table 105.2). Germinomas label with placental alkaline phosphatase and may occasionally seed the CSF.

The NGGCTs are highly malignant and more aggressive than germinomas; they metastasize to the CSF more frequently than germinomas. Choriocarcinoma contains cyto- and syncytiotrophoblastic cells that produce β-hCG. Endodermal sinus tumors contain yolk sac elements that produce AFP. High levels of β-hCG or AFP in the CSF or serum indicate the presence of malignant germ cell elements. When markers are elevated, a tissue diagnosis is not necessary and patients are treated with radiation and chemotherapy.

All patients with histologically confirmed GCTs, regardless of subtype, should have serum and CSF tested for β-hCG and AFP (if not done preoperatively), a complete spine magnetic resonance imaging (MRI) with gadolinium, and cytologic examination of CSF to complete staging prior to treatment.

Treatment first involves surgical resection to establish the diagnosis and debulk the tumor; if possible, gross total excision is the surgical goal. Patients with pure germinomas should be treated with radiotherapy, usually 36 to 45 Gy; the port must include 24 Gy to the whole ventricular system. If the tumor is disseminated in the CSF, craniospinal radiation is required. Chemotherapy may be useful at recurrence but is not recommended at diagnosis because most germinoma patients are cured with radiotherapy alone. The NGGCTs are relative insensitive to radiation and therefore require craniospinal radiotherapy with adjuvant chemotherapy in all cases after maximal resection. Benign GCTs such as teratomas, dermoids, and epidermoids are generally curable with surgery alone.

Pineal Cell Tumors

Primary pineal cell tumors are classified as low-grade pineocytomas (World Health Organization [WHO] grade I), pineal parenchymal tumors of intermediate differentiation (WHO grade II or III), or the highly malignant pineoblastoma (WHO grade IV). The higher grade tumors tend to occur in children and young adults, whereas pineocytomas usually occur in adults. Pineal tumors of all histologic grades may seed the leptomeninges, but pineocytomas do so only rarely. Complete resection of a pineocytoma does not require additional therapy, but incomplete resection should be followed by radiation. Intermediate-grade pineocytomas require radiotherapy, and pineoblastomas require neuraxis radiation and chemotherapy.

Gliomas

Gliomas account for one-third of pineal tumors. Most are invasive and have a prognosis comparable to astrocytomas of the upper brainstem. Some gliomas are low grade, cystic, and may be surgically curable. Anaplastic astrocytomas and glioblastomas are less common. Oligodendrogliomas and ependymomas may also occur. Treatment of these tumors is identical to the treatment of gliomas in other areas of the central nervous system.

Meningiomas

Meningiomas may arise from the velum interpositum or from the tentorial edge. They occur predominantly in middle-aged patients and in the elderly. Meningiomas make up approximately 8% of pineal region tumors but overall account for less than 1% of all meningiomas. They are amenable to surgical resection.

Metastasis and Other Miscellaneous Tumors

The pineal gland does not have a blood-brain barrier and, like the pituitary gland, may be underrecognized as a site of brain metastasis from systemic tumors. Miscellaneous tumors include sarcoma, hemangioblastoma, choroid plexus papilloma, lymphoma, and chemodectoma.

Pineal Cysts

Benign cysts of the pineal gland are often found incidentally on imaging studies, and it is important to distinguish them from cystic tumors. They are normal variants of the pineal gland and consist of a cystic structure surrounded by normal pineal parenchymal tissue (Fig. 105.1). Radiographically, they are up to 2 cm in diameter and often have some degree of peripheral enhancement as a result of the compressed normal pineal gland. Pineal cysts may be found in 4% of all MRI scans. These cysts are static, anatomic

FIGURE 105.1 Sagittal T1-weighted gadolinium-enhanced magnetic resonance imaging (MRI) of a pineal cyst. These cysts may have rim enhancement (*small arrow*) and may be up to 2 cm in diameter. They rarely cause compression of the sylvian aqueduct (*larger arrow* on patent aqueduct) and are rarely symptomatic. Histologically, they are normal variants of the pineal gland and require no treatment; they must be distinguished from cystic tumors. Growth of the cyst on serial MRIs or the development of hydrocephalus is sufficient cause to doubt the diagnosis, and surgical resection should be considered.

FIGURE 105.2 Sagittal magnetic resonance imaging with gadolinium showing multicentric germinoma involving the pineal region and infiltrating the mammillary bodies, optic chiasm, and pituitary stalk. This patient presented with diminished visual fields and diabetes insipidus.

variants and need no treatment unless they become symptomatic. The most common symptoms are headaches, followed by visual symptoms. The cysts may be sufficiently large to cause obstructive hydrocephalus. Decompression can occasionally be accomplished by third ventricular endoscopic resection of the cyst.

CLINICAL FEATURES

Pineal region tumors may become symptomatic from one of three mechanisms: increased intracranial pressure from hydrocephalus, direct compression of brainstem and cerebellum, or endocrine dysfunction. Headache, associated with hydrocephalus, is the most common symptom at onset and is caused by obstruction of third ventricular outflow at the aqueduct of Sylvius. Leptomeningeal dissemination can produce a multitude of symptoms depending on the area affected, analogous to leptomeningeal metastases from other cancers.

More advanced hydrocephalus may result in papilledema, gait disorder, nausea, vomiting, lethargy, and memory disturbance. Direct midbrain compression may cause disorders of ocular movements, such as Parinaud syndrome (paralysis of upgaze, convergence or retraction nystagmus, and light-near pupillary dissociation) or the sylvian aqueduct syndrome (paralysis of downgaze or horizontal gaze superimposed upon a Parinaud syndrome). Either lid retraction (Collier sign) or ptosis may follow dorsal midbrain compression or infiltration. Fourth nerve palsy with diplopia and head tilt may be seen. Ataxia and dysmetria may result from direct cerebellar compression.

Endocrine dysfunction is rare, usually arising from secondary effects of hydrocephalus or tumor spread to the hypothalamic region (Fig. 105.2). The symptoms may occur early, before any radiographic documentation of hypothalamic seeding.

Although precocious puberty has been linked with pineal masses, documented cases are rare. Precocious puberty is actually precocious pseudopuberty because the hypothalamic-gonadal axis is not mature. It occurs in boys with choriocarcinomas or germinomas with syncytiotrophoblastic cells and ectopic secretion of β-hCG. In boys, the luteinizing hormone–like effects of β-hCG may stimulate Leydig cells to produce androgens that induce development of secondary sexual characteristics and pseudopuberty. This phenomenon does not occur in girls with pineal region tumors because GCTs are rare in females, and both luteinizing hormone and follicle-stimulating hormone are necessary to trigger ovarian estrogen production.

DIAGNOSIS

The MRI with gadolinium is mandatory for all pineal tumors to determine the presence of hydrocephalus and evaluate tumor size, vascularity, and homogeneity. In particular, sagittal MRI reveals the relationship of the tumor to surrounding structures and also evaluates possible ventricular seeding. Angiography is not performed unless a vascular anomaly is suspected. Measurement of AFP and β-hCG in serum and CSF is required in the preoperative workup. If β-hCG or AFP levels are elevated, malignant germ cell elements must be present so a tissue diagnosis is not necessary and treatment with radiation and chemotherapy can commence. Despite improved imaging and CSF markers, a definite histologic diagnosis requires pathologic examination of tumor tissue, and all patients should undergo surgery.

MANAGEMENT

Given the rarity of pineal region tumors, studies establishing level 1 standards do not exist. Owing to the wide variety of pineal region tumor subtypes, the general approach to these tumors is to first establish a histologic diagnosis by obtaining tumor tissue through an open surgical approach or a stereotactic-guided needle biopsy (Fig. 105.3). Subsequent management is dependent on the tumor type (Fig. 105.4).

FIGURE 105.3 Axial **(A)** and sagittal **(B)** magnetic resonance imaging scans with gadolinium of a heterogeneously enhancing pineal region tumor. **C:** The tumor comprised several germ cell elements, including immature teratoma, germinoma, endodermal sinus tumor, and embryonal cell carcinoma. Pineal region tumors may be extremely heterogeneous, and extensive tumor sampling is necessary to avoid diagnostic errors.

Management of Hydrocephalus

Hydrocephalus is present in most pineal tumor patients and must be surgically addressed, preferably by an endoscopic third ventriculostomy. A ventriculoperitoneal shunt is an acceptable alternative but carries greater long-term risks including peritoneal seeding of malignant tumors.

Surgery

The pineal region may be reached surgically from one of several approaches, above or below the tentorium, depending on tumor size and coexistent hydrocephalus (**Fig. 105.5**). Complete excision is the goal for any pineal tumor. Nearly one-third of pineal tumors are benign and curable with complete resection alone. With malignant tumors, aggressive tumor resection provides the best opportunity for accurate histologic diagnosis and may increase the effectiveness of adjuvant radiotherapy or chemotherapy. The overall operative mortality is about 4%, with an additional 3% permanent major morbidity. The most serious complication of surgery is hemorrhage into a partially resected malignant tumor. The most common postoperative complications usually transient and include ocular palsies, altered mental status, and ataxia. For patients with obviously disseminated tumor or those with medical problems that pose excessive surgical risks, biopsy via a stereotactic or endoscopic approach is a reasonable alternative for obtaining diagnostic tissue. Although gaining in popularity, stereotactic biopsy is not performed routinely because of possible sampling error through insufficient tissue analysis, increased risk of hemorrhage from the adjacent deep venous system and highly vascular pineal tumors, and a better prognosis that follows aggressive resection.

FIGURE 105.4 Algorithm for management of pineal region tumors. Abbreviations: CSF, cerebrospinal fluid; MRI, magnetic resonance imaging.

Postoperative Staging

All patients with pineal cell tumors and GCTs are evaluated for CSF seeding (**Fig. 105.6**). High-resolution gadolinium-enhanced MRI of the complete spine should be performed. Even if the spine MRI is negative, CSF analysis for cytology and markers is recommended to look for microscopic disease.

Radiotherapy

Germinomas and pineal parenchymal tumors of intermediate differentiation require radiation to a dose of 36 to 45 Gy with coverage of the ventricles. All patients with pineoblastomas, NGGCT, and disseminated germinomas require neuraxis radiotherapy, usually to a total dose of about 36 Gy, with a boost to the primary site to achieve a dose of at least 54 Gy. Gliomas are treated according to histologic subtype.

Although generally considered safe, long-term follow-up results with stereotactic radiosurgery are limited because pineal tumors are rare. There are reports of tumor control using radiosurgery as the sole treatment for some low-grade tumors such as pineocytoma, but it rarely produces complete tumor regression and is probably not optimal initial therapy unless surgery is contraindicated. The main problem with radiosurgery is not the response of the targeted mass but the potential for recurrence outside of the treatment volume. It has been used with some success for tumors less than 3 cm in diameter at recurrence, provided there is no evidence of CSF dissemination.

Chemotherapy

Chemotherapy has been of most benefit with NGGCTs and pineoblastomas. The most commonly used regimens are combinations of cisplatin, vinblastine, and bleomycin or cisplatin and VP-16 (eg, etoposide). Often a combined neoadjuvant chemotherapy with RT is used as it significantly improved outcomes in patients with NGGCT, although results remain inferior to that for patients with germinoma. In the absence of a prospective randomized study, neoadjuvant chemotherapy followed by CSI remains the standard of care for all patients with intracranial NGGCTs. Young children are treated with chemotherapy alone, and radiotherapy is deferred until they are at least 3 years or older because of the risk of severe, long-term effects on growth and cognition. Initial attempts to avoid radiation in all patients by using aggressive chemotherapy resulted in an unacceptably high incidence (50%) of recurrence at 2 years, including patients with germinoma, which is curable with radiation alone. Therefore, chemotherapy is not used as part of the initial treatment of localized germinomas.

FIGURE 105.5 Axial flair without gadolinium **(A)** and sagittal T1 with gadolinium **(B)** magnetic resonance imaging scans (MRIs) of a mixed dermoid/germinoma causing hydrocephalus. **C:** Germinoma is seen on the left side of this hematoxylin- and eosin-stained section, in the form of cords and nests of large cells with round nuclei, prominent nucleoli, and abundant clear cytoplasm associated with a reactive lymphoid cell population. On the right side is a cystic area partially lined by squamous epithelium and filled with keratin, compatible with a teratomatous component. (Courtesy of Drs. George Zanazzi and Peter Canoll.) **D:** Postoperative MRI after tumor removal.

OUTCOME

Generally, benign pineal tumors and growing pineal cysts are curable with surgery alone. For malignant tumors, meta-analysis of small clinical series suggests that maximal surgical resection provides survival benefits; however, level 1 or 2 evidence is lacking. Prognosis is highly dependent on tumor histology. Germinomas have a 90% 10-year survival rate following surgery and radiotherapy, and therefore, aggressive surgical resection is not indicated. Patients with NGGCT have 5-year survival rates in the range of 50%, and the prognosis for patients with recurrent intracranial NGGCTs is generally poor. Greater than 80% of patients with pineocytomas survive 5 years particularly following aggressive surgical resection. Median survival for patients with pineoblastomas is much more variable ranging from 1 to 5 years, with prognosis influenced by extent of resection, age, and disseminated disease. The outcome for patients with glial tumors is similar to gliomas found in other regions of the brain.

106 Acoustic Neuroma and Other Skull Base Tumors

Randy S. D'Amico and Michael B. Sisti

KEY POINTS

1. Acoustic neuromas are benign, slow-growing tumors that are treated with a combination of observation, surgical resection, and radiosurgery with excellent outcomes in the hands of experienced practitioners.
2. Skull base pathology is variable and challenging to treat given its proximity to critical neural and vascular structures.
3. Modern treatment of skull base pathology focuses on the preservation of neurologic function.
4. Advanced radiotherapies such as stereotactic radiosurgery has improved the control of many skull base pathologies.

VESTIBULAR SCHWANNOMA (ACOUSTIC NEUROMA)

Epidemiology

Vestibular schwannomas (eg, acoustic neuroma, acoustic neurofibroma) are slow-growing, benign extra-axial tumors that originate commonly from the superior vestibular portion of the eighth cranial nerve (CN VIII). Vestibular schwannomas comprise 8% to 10% of intracranial tumors. Tumors may arise either sporadically (95%) or in association with neurofibromatosis type 2 (NF2). The incidence of sporadic cases is believed to be 1 per 100,000 person-years, with a median age of 50 years. As a result of the prevalence of magnetic resonance imaging (MRI), the incidence of vestibular schwannomas has increased recently, whereas the typical size at diagnosis has decreased.

Pathobiology

Vestibular schwannomas are histopathologically benign tumors that grow slowly from the Schwann cell sheath surrounding the vestibular branch of CN VIII. Tumors are composed of Antoni A (narrow elongated bipolar cells) and Antoni B fibers (loose reticulated pattern of cells). Verocay bodies are frequently seen and consist of acellular eosinophilic areas surrounded by parallel arrangements of spindle-shaped Schwann cells.

Vestibular schwannomas are typically unilateral lesions. Bilateral vestibular schwannomas occur in less than 5% of patients and are a defining characteristic of NF2, an autosomal dominant disorder involving the *NF2* gene located on chromosome 22 band q11-13.1. This gene normally encodes the protein merlin (schwannomin), which is thought to play a role in membrane stability through interactions with cytoskeletal and integral membrane proteins. Loss of function of merlin in Schwann cells has been associated with both sporadic and NF2-related vestibular schwannomas, and the gene is often considered a classic tumor suppressor. Cytologically, vestibular schwannomas that arise in NF2 are identical to sporadic cases but with a greater tendency to infiltrate the nerve rather than displace it. In addition to patients with bilateral lesions, any patient younger than 40 years of age with a unilateral vestibular schwannoma should also undergo evaluation for NF2.

Tumors often originate within the internal acoustic meatus (intracanalicular) and may extend into the cerebellopontine angle (extracanalicular; Fig. 106.1). Mass effect from extracanalicular tumor may compromise function of cranial nerves, brainstem nuclei, and the cerebellum. Tumors typically follow three growth patterns: (1) no or very slow growth, (2) slow growth (2 mm/y linear growth on imaging studies), or (3) fast growth (>8 mm/y) as a result of the enlargement of cystic components or rarely intratumoral hemorrhage.

Diagnosis

Vestibular schwannomas most commonly present with progressive unilateral hearing loss, characterized by difficulty with speech discrimination, especially when talking on the telephone. The next most common symptoms include tinnitus, followed by balance difficulties. This triad of symptoms is related to pressure on the eighth nerve complex in the internal auditory canal. Other presenting symptoms include facial paralysis, trigeminal neuralgia, and rarely hydrocephalus and brainstem compression in the setting of larger tumors. Although this constellation of symptoms may occur with any mass in the cerebellopontine angle, including meningiomas, cholesteatomas, or trigeminal neuromas, these lesions will rarely cause tinnitus or hearing dysfunction.

Patients with hearing loss often undergo audiometric evaluation with pure tone audiogram and speech discrimination evaluation. Those with vestibular disturbances may undergo vestibular testing. Hearing loss is typically insidious and progressive, with 70% of patients demonstrating a high-frequency loss pattern and impaired word discrimination (especially noticeable in telephone conversation). Tinnitus is usually high-pitched. Weber test lateralizes to the uninvolved side, and Rinne test will be positive on both sides if there is enough preserved hearing.

Asymmetric sensorineural hearing loss, or deficits in other cranial nerves, indicates the need for imaging. Gadolinium-enhanced MRI is the gold standard for diagnosing vestibular schwannomas. Tumors enhance brightly, and an origin within the internal auditory canal suggests vestibular schwannoma rather than meningioma. Contrast-enhanced computed tomography (CT) can also be used to diagnose vestibular

FIGURE 106.1 Vestibular schwannoma. **A:** T1-weighted axial magnetic resonance imaging before contrast shows large hypointense mass within the cerebellopontine angle exerting mass effect on the brainstem. **B:** T1-weighted axial magnetic resonance imaging postcontrast shows a vestibular schwannoma with expansion of the internal auditory meatus causing mass effect on the pons and cerebellum.

schwannomas greater than 15 mm in diameter for patients who cannot undergo MRI.

Management and Outcomes

The goal of treatment for vestibular schwannomas is to cure the tumor while preserving intact neurologic function. Following diagnosis, patients with vestibular schwannomas have several options for managing their tumor including observation with serial imaging, stereotactic radiosurgery, fractionated radiotherapy, and microsurgery. Selection of treatment modality depends on tumor size, symptoms, patient age, patient health, and patient preference. Figure 106.2 represents a decision tree following diagnosis of vestibular schwannoma. In general, noncystic, non-NF2 intracanalicular tumors or cerebellopontine tumors 20 mm or smaller may be followed with serial imaging and hearing tests. Tumors larger than 15 to 20 mm should be treated. The NF2 patients present a challenge and should be evaluated on a case-by-case basis.

Observation/Expectant Management

Observation with serial clinical assessment and follow-up MRI to monitor for signs of tumor growth is an option in the

FIGURE 106.2 Treatment algorithm for vestibular schwannoma management.

management of vestibular schwannoma. Patients utilizing this approach are monitored using MRI until progression of symptoms or tumor growth warrants more invasive treatment. Imaging is recommended annually until year 5 after diagnosis with interval lengthening thereafter with tumor stability. However, observation is not without risk because tumor growth rates and progression of symptoms are not predictable. By 10 years, most clinical experience demonstrates that the majority of patients will have tumor growth and progression of symptoms. Therefore, the "wait and scan" approach should mainly be used in older patients and those whose medical comorbidities preclude other treatment options.

Stereotactic Radiosurgery

Radiosurgery is a therapeutic option that improves tumor control and hearing preservation compared with observation in patients presenting with small tumors (<30 mm diameter), serviceable hearing, or in those who wish to avoid surgery due to preference or anxiety. A dose of 12 to 13 Gy is prescribed typically and associated with improved hearing preservation. Long-term tumor control rates ranging from 91% to 98% have been reported in large series after radiosurgery, with 1.6% to 4.2% ultimately requiring resection for progressive enlargement. Individuals with sporadic vestibular schwannomas who have documented serviceable hearing in the ipsilateral ear receiving single-fraction stereotactic radiation up to 13 Gy to the tumor margin have greater than 50% to 75% chance of hearing preservation up to 5 years and a greater than 25% to 50% chance of hearing preservation at 10 years—with higher rates achievable with intracanalicular tumors. Minimizing the radiation exposure to nearby structures (ie, the cochlea, semicircular canals, and brainstem in larger tumors) minimizes morbidity rates associated with radiosurgery without sacrificing efficacy. Preservation of facial and trigeminal nerve function is also possible in the majority of patients.

For smaller tumors, hearing preservation and tumor control rates are equivalent following radiosurgery or surgical resection. However, radiosurgery is more effective than surgical resection in preserving postoperative facial function and is associated with lower rates of trigeminal neuropathy and other treatment-associated morbidity. In addition, hospital lengths of stay and management costs are less after radiosurgery and in general, postoperative functional outcomes and patient satisfaction have been found to be greater after radiosurgery when compared with microsurgery.

Advances in technology for noninvasive stereotactic radiosurgery allow using a thermoplastic mask to immobilize select patients for multisession or fractionated radiation. The opportunity to use fractionation for vestibular schwannoma patients permits lower doses to healthy brain and inner ear structures. Studies are ongoing to evaluate the long-term efficacy of this method on hearing preservation and tumor control.

Surgical Resection

Microsurgical resection remains the best cytoreductive therapy for vestibular schwannomas and is generally indicated in the setting of tumor progression after previous interventions and for those with large tumors (>30 mm diameter). In particular, microsurgery remains the preferred treatment for large lesions causing mass effect and obstructive hydrocephalus. Additional treatment is necessary in less than 2% of cases after microsurgical treatment. Facial nerve function may be preserved in more than 95% of patients with small tumors less than 20 mm, with rates of preservation dropping in the setting of tumors larger than 30 mm.

Maintenance of serviceable hearing following microsurgical resection is less probable, and patients should be counseled appropriately. Serviceable hearing, otherwise known as *useful hearing*, is assessed using the combined results of pure tone audiogram that evaluates the functionality of hearing and speech discrimination tests. Current guidelines suggest that in adults with small- to medium-sized (<20 mm) sporadic vestibular schwannomas, there is a greater than 25% to 50% chance of hearing preservation following surgical resection with improved rates in smaller tumors. Planned near-total or extensive subtotal resections, followed by radiosurgery for residual tumor, may be appropriate for large tumors, with excellent rates of facial nerve preservation and functional outcomes and no decrease in tumor control.

Chemotherapy

Patients with progressive acoustic neuromas in the setting of NF2 may derive benefit from treatment with bevacizumab, an anti–vascular endothelial growth factor monoclonal antibody. Treatment with bevacizumab may reduce the size of the tumor or prolong tumor stability in patients with NF2 without surgical options. Treatment may also improve hearing or prolong time to hearing loss in these patients with minimal associated morbidity. Additional chemotherapeutic options such as lapatinib or everolimus may also be considered.

MALIGNANT TUMORS OF THE SKULL AND SKULL BASE

Metastasis to the Skull Base

Epidemiology

The skull is a common site of metastases from systemic cancers, with skull metastases occurring in 4% of cancer patients. The most common metastatic tumors to the skull base include breast, lung, and prostate cancers. Not surprisingly, prostate carcinoma is the most frequent cause of skull metastases in men, whereas breast carcinoma is the most common in women. Colon, renal, and thyroid cancers, as well as lymphoma, melanoma, and neuroblastoma, may also metastasize to the skull base.

Diagnosis

The clinical manifestation of metastases to the skull base depends on the location of the lesion. Cranial nerves are vulnerable to compression by osseous metastases as they exit through the bony foramina of the skull. In addition, although metastases to the skull base are often painless, craniofacial pain in a patient with known cancer may be an initial symptom.

Contrast-enhanced MRI is the gold standard for detection of metastases to the skull base. A CT scan is less effective than MRI for detecting contrast-enhancing soft-tissue masses but is the best method to demonstrate lytic bone lesions. Radionuclide bone scans have great sensitivity in detecting bone metastases. Although biopsy may be difficult and hazardous, it may be necessary to establish a diagnosis. Examination of cerebrospinal fluid (CSF) may be important to evaluate meningeal carcinomatosis in select patients.

Management and Outcomes

The prognosis of skull base metastases depends on the extent of the primary disease, the location and associated extension of the tumor, and the surgical accessibility of the metastasis itself. In addition to symptomatic treatments with steroids and analgesia, specific treatments include radiotherapy, chemotherapy, and surgery. Treatment depends on the nature of the underlying tumor. Palliative radiotherapy is generally the standard treatment with a total dose of at least 30 Gy given in 3 Gy fractions with excellent symptomatic relief. Some patients benefit from chemotherapy or hormonal therapy for appropriately sensitive tumors. Stereotactic radiosurgery is useful for small tumors or tumors previously irradiated. Select patients may benefit from surgical resection. In general, the overall prognosis is poor with median survival less than 3 years for most tumors. Note that metastases to the skull are not synonymous with metastases to the brain and are not protected by the blood-brain barrier, an important consideration when choosing chemotherapeutics.

Extension of Malignant Tumors to the Skull Base

Several malignant tumors involve the skull base by direct extension (**Fig. 106.3**). These include squamous cell carcinoma (nasal sinuses and temporal bone), adenoid cystic carcinoma (salivary glands), esthesioneuroblastoma (olfactory mucosa), and nasopharyngeal carcinoma. Involvement of the skull base by these tumors may result in pain and cranial neuropathies. Erosion of the skull base and the presence of a contrast-enhancing soft-tissue mass are generally identified on CT or MRI. Biopsy of accessible lesions is diagnostic, and small tumors may be cured by wide excision prior to invasion of sensitive neural structures. Management relies on a multidisciplinary approach. However, most tumors are extensive at the time of diagnosis, and prognosis is poor despite radical excision and radiation therapy.

FIGURE 106.3 Esthesioneuroblastoma. Coronal magnetic resonance imaging demonstrates an esthesioneuroblastoma in the ethmoid sinus with intradural extension *(arrow)*. This tumor arises from olfactory mucosa.

Primary Malignant Tumors of the Skull and Skull Base

Chondrosarcoma

Chondrosarcoma is a malignant cartilage tumor originating in areas of endochondral ossification within the cranial base that most commonly affects men in the fourth decade. Tumors arise in the paranasal sinuses, the parasellar areas, or the cerebellopontine angle, with variable symptoms depending on location. The CT and MRI are the preferred imaging modalities. Maximal safe debulking is considered first-line therapy. Histologically, chondrosarcomas are classified into conventional, dedifferentiated clear cell, and mesenchymal subtypes and these histology-based grading systems have been shown to predict prognosis. There remains variability in the literature regarding indications for observation versus adjuvant radiotherapy following surgical management.

Chordoma

Chordoma is a rare, histologically benign, locally aggressive bone tumor associated with destruction of surrounding tissues. Derived from remnants of notochord within the axial skeleton, tumors distribute equally between the skull base, mobile spine, and sacrum with predominance in men between 50 and 60 years of age. Chordomas of the skull base often arise in the clivus and present with cranial nerve palsies. Histologically, tumors are distinguished by the presence of physaliferous cells. Treatment involves aggressive maximal safe resection followed by advanced radiotherapy such as stereotactic radiosurgery or proton beam radiation. High rates of progression and recurrence make their prognosis similar to malignant tumors.

Osteogenic Sarcoma

Osteogenic sarcoma (osteosarcoma) is the most common primary bone malignancy. Osteosarcoma primarily affects long bones with rare involvement of the skull or skull base. Lesions are the result of osteoid or immature bone production by malignant spindle cells and are associated with destruction of normal bone (**Fig. 106.4**). Patients may report a history of prior radiation, chemotherapy, Paget disease, fibrous dysplasia, or chronic osteomyelitis. Symptoms vary with location along the skull base. Treatment is maximal safe surgical resection with an emphasis on preserving neurologic function and avoiding cosmetic defects. Tumors are relatively radioresistant and chemotherapy with cisplatin, doxorubicin, and high-dose methotrexate may offer benefits.

Soft-Tissue Sarcoma

Soft-tissue sarcomas of the skull base are rare. Malignant fibrous histiocytoma, fibrosarcoma, angiosarcoma, and malignant peripheral nerve sheath tumors are the most frequently encountered lesions. The CT and MRI are essential for assessing tumor size and location. Treatment is aggressive safe resection. However, because anatomic constraints of the skull base often limit wide excision, patients will often receive adjuvant radiotherapy and chemotherapy.

FIGURE 106.4 Osteogenic sarcoma (osteosarcoma). **A:** Noncontrast axial computed tomography shows a calcified mass within the medial right parietooccipital lobes with massive extracranial soft-tissue swelling. **B:** Corresponding bone window shows thinning and eroded calvarium with several large areas of calcification and ossification noted within the extracranial soft tissues in the right parietooccipital region. These findings are classic for osteosarcoma.

Glomus Jugulare Tumors

Jugular paragangliomas ("glomus jugulare") are the most common tumor arising within the jugular foramen. These rare, slow-growing, locally invasive, and highly vascular tumors arise from chromaffin cells in the region of the jugular bulb and course along the glossopharyngeal nerve, the tympanic branch of the glossopharyngeal nerve (Jacobson nerve), or the auricular branch of the vagus nerve (Arnold nerve). Tumors present as a result of both compression and infiltration of the adjacent temporal and occipital bone with subsequent involvement of nearby cranial nerves. Tumors may extend into the middle ear and cause conductive hearing loss, pulsatile tinnitus, and audible bruits, or may be discovered as a small vascular mass within the middle ear cavity. An MRI with contrast best visualizes tumors, and magnetic resonance angiography reveals their extensive vascularity. A CT with contrast is considered in patients who cannot undergo MRI. Digital subtraction angiography is performed for diagnosis, and embolization is essential to decrease tumor vascularity and facilitate resection. Some paragangliomas secrete catecholamines, which may be ascertained by a 24-hour urine assay and must be blocked prior to surgery. Malignant transformation of these lesions is rare.

Surgery offers the best chance of cure for glomus jugulare tumors. Gross total resection results in cessation of cardiovascular symptoms and normalization of catecholamine levels in patients symptomatic from secreting tumors. However, total removal is difficult and accompanied by significant morbidity due to the vascularity and invasiveness of the lesions. Observation is appropriate until patients become symptomatic or tumors demonstrate growth on imaging. Stereotactic radiosurgery may offer improved rates of tumor control with lower risks of morbidity compared with surgery for patients with nonsecreting tumors.

BENIGN TUMORS OF THE SKULL

Osteoma

Osteomas are rare, benign, slow-growing tumors of the skull. Histologically, tumors are composed of well-differentiated mature, compact, or cancellous bone arising from either the inner or outer table of the skull. Lesions frequently occur in the paranasal sinuses but may arise within the frontoethmoidal region, the petrous bone (mastoid sinuses), the cranial vault, and the mandible. Tumors are generally asymptomatic but may be associated with headache and recurrent sinusitis. Proptosis and orbital deformities occur secondary to orbital invasion by the tumors. Rarely, tumors present with pneumocephalus, rhinorrhea, meningitis, dural erosion, and abscess formation. Calvarial lesions are hard, painless masses with minimal intracranial extension. Diagnosis is based on the characteristic appearance of a circumscribed homogenous hyperdensity involving the skull that is best seen with CT scan (**Fig. 106.5**). Symptomatic lesions are treated with surgical resection, and reconstruction may be necessary for extensive lesions.

Chondroma

Chondromas are rare, slow-growing benign tumors arising from cartilage rests at the basilar synchondroses of the skull base. Lesions have a predilection for the sphenoethmoidal, sphenopetrosal, sphenooccipital, or petrooccipital regions. However, rare dural, intraparenchymal, and intraventricular lesions have been described. Clinical presentation varies by anatomic location and slow-growing tumors may remain asymptomatic for prolonged periods of time. Radiographically, tumors appear as lytic lesions,

FIGURE 106.5 Orbital osteoma. Coronal (A) and axial (B) computed tomography with bone windows show an osteoma involving the orbit.

with sharp margins and erosion of surrounding bone. Stippled calcification within the lesion may be apparent and helps distinguish chondroma from metastasis or chordoma. Chondromas typically display high intensity on T2-MRI and low to intermediate intensity on T1-MRI, with a heterogeneous ring-and-arc enhancement pattern after administration of gadolinium. Treatment involves radical resection for symptomatic lesions with extension to normal bone margins to prevent recurrence. Progression to malignant chondrosarcoma is rare.

Hemangioma

Hemangiomas are benign, vascular bone tumors representing 0.2% of bony neoplasms of the skull. Lesions may involve the calvaria or the skull base (or vertebral bodies of the spine), with a predilection for the cavernous sinus. Commonly discovered incidentally after CT or MRI performed for other reasons, hemangiomas may present as a slowly enlarging lump associated with headaches that worsen with lesion expansion. However, neurologic findings are uncommon because hemangiomas rarely extend intracranially. Radiographically, tumors appear as well-circumscribed, expansive hypodense regions with a honeycomb or polka-dotted pattern on CT. An MRI demonstrates heterogeneous signal on both T1- and T2-weighted sequences and may demonstrate flow voids suggestive of a vascular lesion. However, the radiographic appearance of skull base hemangiomas is variable, and pathologic examination is often required for diagnosis. Resection is indicated for neurologic compromise, unremitting headache, mass effect, cosmetic deformity, or tissue diagnosis. Treatment is by safe maximal resection, and the use of preoperative embolization may be beneficial. The use of radiation for incompletely resected, or multiple tumors, remains controversial.

Dermoid and Epidermoid Tumors

Dermoid and epidermoid cysts are benign, extra-axial developmental lesions arising from trapped ectodermal tissue during closure of the neural tube. Cysts are lined with stratified squamous epithelium and contain keratin, cellular debris, cholesterol (epidermoids), and elements of the dermis, including hair and sebaceous glands (dermoids). Epidermoids most commonly arise in the cerebellopontine angle and the parasellar region but also occur in the middle cranial fossa and spinal canal (Fig. 106.6). Dermoids are predominantly midline lesions, arising commonly in the diploe of the fontanel extradurally and in the parasellar region intradurally.

Cysts may remain asymptomatic for years due to slow growth, with rare acute presentations due to hemorrhage or trauma. Cyst rupture is a rare complication that can cause severe chemical or aseptic meningitis. Epidermoids and dermoids typically have the appearance of hypodense areas on CT. On MRI, epidermoids present as polycystic irregular lesions with extensive growth in the CSF spaces. Epidermoids have slightly higher signal intensity than CSF on T1- and T2-weighted images and heterogeneous features on fluid-attenuated inversion recovery sequences. Diffusion-weighted imaging facilitates identification of epidermoids. Dermoids are usually hyperintense on both T1- and T2-weighted images. Radical surgical excision is the preferred treatment when possible for dermoids and epidermoids and can be curative. However, tumors are often densely adherent to cranial nerves and vascular structures. Given their slow-growing and benign nature, the primary surgical objective is then to decompress the mass by evacuating the cyst contents and removing nonadherent portions of the capsule while not manipulating cranial nerves or vascular structures to the extent that there may be permanent damage. Malignant degeneration is rare.

NEOPLASTIC-LIKE LESIONS OF THE SKULL

Hyperostosis

Hyperostosis of nonneoplastic etiology may involve either the inner or the outer table of the skull. Outer table hyperostosis is clinically insignificant aside from cosmetic concerns.

FIGURE 106.6 Epidermoid. Epidermoids are often indistinguishable from arachnoid cysts or dilated cerebrospinal fluid (CSF) spaces on magnetic resonance imaging sequences. These nonenhancing lesions are usually isointense to CSF on both postcontrast, T1-weighted images **(A)**, and T2-weighted images **(B)** with associated mass effect in larger lesions as demonstrated by this epidermoid of the cerebellopontine angle. **C:** Diffusion-weighted imaging sequences help to differentiate these lesions from CSF.

Hyperostosis of the inner table may rarely become large enough to compress intracranial contents. Hyperostosis frontalis interna is a condition occurring in postmenopausal women, characterized by increased bone deposition along the inner table of the frontal bone. Hyperostosis frontalis interna is usually an incidental finding on CT or MRI, although excessive growth can cause compression of brain tissue.

Fibrous Dysplasia

Fibrous dysplasia is a benign condition in which normal bone is replaced by poorly organized woven bone. Progressive growth of lesions may result in swelling, cosmetic deformities, and pain. Fibrous dysplasia is most commonly monostotic with involvement of a single bone. However, 25% of cases are polyostotic involving more than 50% of the skeleton and can be associated with fractures and skeletal deformities. Fibrous dysplasia may also occur as part of McCune-Albright syndrome. Lesions mostly occur in the ribs or craniofacial bones, particularly the maxilla. Localized involvement of the skull base and sphenoid wing, particularly by the sclerotic variety, may cause symptoms secondary to cranial nerve entrapment. X-rays and CT classically demonstrate a ground-glass appearance due to thin spicules of woven bone (Fig. 106.7). Chemotherapy and radiation are not effective treatments, and radiation may predispose to higher rates of malignant transformation. Neurosurgical involvement may be required for skull lesions producing refractory pain or neurologic symptoms.

FIGURE 106.7 Fibrous dysplasia. Axial **(A)** and coronal **(B)** computed tomography with bone windows demonstrate classic ground-glass appearance of fibrous dysplasia of the orbit and ethmoid sinus.

FIGURE 106.8 Mucocele. **A:** Coronal contrast-enhanced magnetic resonance imaging shows a large mucocele compressing the frontal lobe, with chronic inflammation of the nasal mucosa obstructing the nasal sinuses. **B:** Intraoperative photograph shows the mucocele before its resection and subsequent skull base reconstruction. The frontal sinus contains inflammatory tissue *(arrow)* that had caused obstruction of the sinus.

Paget Disease (Osteitis Deformans)

Paget disease is a disorder of osteoclasts causing rapid remodeling of bone. Increased bone resorption is followed by reactive osteoblastic overproduction of sclerotic, brittle woven bone that produces a characteristic mosaic pattern on x-ray. Family history is present in 15% to 30% of discovered cases and about 1% degenerate into sarcoma with the possibility of systemic metastases. Lesions commonly involve the axial skeleton, long bones, and the skull. Mostly asymptomatic or incidentally discovered, facial and skull base remodeling may result in localized pain, cranial nerve compression with deafness being the most prominent finding in most cases, or basilar invagination. Markedly elevated serum alkaline phosphatase is a constant feature. Surgical intervention should be reserved for diagnosis or relief of symptoms.

Mucocele

Occlusion of a nasal air sinus may result in an encapsulated collection of mucus or pus, known as a *mucocele*. Progressive expansion of mucoceles may result in erosion through the skull base with subsequent compression of intracranial contents. Lesions frequently enhance with intravenous contrast on MRI and CT (Fig. 106.8). Surgery with reconstruction is the treatment of choice.

Miscellaneous

A variety of systemic disease may additionally involve the skull. These include histiocytosis X (eosinophilic granuloma is the mildest form), multiple myeloma, plasmacytoma, brown tumor of hyperparathyroidism, Wegener granulomatosis, and lethal midline granuloma. Infectious lesions such as tuberculosis, syphilis, leprosy, and fungal infections (especially aspergillosis and mucormycosis) may also occur within the skull base. In addition, lesions within the nose may communicate with the intracranial cavity such as nasopharyngeal carcinoma, esthesioneuroblastoma, encephalocele, and nasal gliomas.

Spinal Tumors 107

David Cachia, Claudio E. Tatsui, and Mark R. Gilbert

KEY POINTS

1. Epidural tumors constitute the most frequent spinal tumors, with metastatic disease making up 95% of these lesions.
2. Spinal cord compression is a neurologic emergency. Treatment should be initiated early, as neurologic status at presentation is predictive of functional outcome.
3. In metastatic epidural disease, there is level 1 evidence that surgery followed by radiation is superior to conventional radiation alone.
4. For intramedullary tumors, the prognosis is related to tumor histology and the occurrence of a plane of surgical dissection between the lesion and the surrounding tissues.

INTRODUCTION

Tumors of the spinal cord or nerve roots are similar to intracranial tumors in cellular type. They may arise from the parenchyma of the cord, nerve roots, meninges, intraspinal blood vessels, sympathetic nerves, or vertebrae. Metastases may arise from remote tumors.

Spinal tumors are divided by location into three groups: intramedullary, extramedullary intradural, or extradural (or epidural) (Fig. 107.1). Occasionally, an extradural tumor extends through an intervertebral foramen to be partially within and partially outside the spinal canal (eg, dumbbell or hourglass tumors; Fig. 107.2).

EPIDEMIOLOGY

Spinal cord tumors are much less prevalent than intracranial tumors, in a ratio of 1:4, but this varies by histology. The intracranial-to-spinal ratio of astrocytoma is 10:1, and the ratio for ependymomas varies from 3:1 to 20:1, although spinal tumors are the most prevalent location of ependymoma in adults. Men and women are affected equally often, except that meningiomas are more common in women and ependymomas are more common in men. Spinal tumors occur predominantly in young or middle-aged adults and are less common in childhood or after age 60 years.

Spinal tumors appear most often in the thoracic region, but if the relative lengths of the divisions of the spinal cord are considered, the distribution is comparatively equal.

PATHOBIOLOGY

The histologic characteristics of primary and secondary tumors are similar to those of intracranial tumors. An analyses of data from the Surveillance, Epidemiology, and End Results and National Program of Cancer Registries that included 11,712 cases of primary spinal tumors identified over a 4-year period showed that of these, 78% were benign and 22% malignant. Histologically, the three most common tumors were meningioma, nerve sheath tumors, and ependymoma.

The most recent Central Brain Tumor Registry of the United States (CBTRUS) data on primary brain and central nervous system tumors showed that in the age group 0 to 19 years, the most common histology were ependymal tumors followed by other neuroepithelial tumors, whereas in the 20 years and older age group, tumors of the meninges predominate (Fig. 107.3).

The most frequent extradural or epidural tumors are metastasis with the most common primary sites of metastatic tumors to the spine being, in order of frequency—lung, prostate, multiple myeloma, and breast. Other common metastatic malignancies include tumors of the gastrointestinal tract, lymphomas, melanomas, kidney, sarcomas, thyroid, and plasmocytomas.

CLINICAL FEATURES

Tumors compressing the spinal cord or the cauda equina typically cause radicular pain. The slow evolution of signs of an incomplete transverse lesion of the cord or signs of compression of the conus medullaris or cauda equina usually bring patients to medical attention. In addition to cord compression, extradural tumors may obstruct the blood supply to the cord; if this occurs, the symptoms are often of sudden onset. In a patient with neurofibromatosis 1 (von Recklinghausen disease), the presence of classical signs such as café au lait spots, axillary or inguinal freckling, and Lisch nodules may focus the differential diagnosis to neurofibroma, glioma, or ependymoma.

The clinical presentation can help the physician localize the area of the spinal cord being affected even prior to any imaging studies are performed. Extramedullary tumors cause symptoms by compressing nerve roots or spinal cord or by occluding the spinal blood vessels resulting in regional ischemia and infarct. The symptoms of intramedullary tumors result from direct interference with the intrinsic structures of the spinal cord from mass effect, edema, or development of syringomyelia. Descriptions of special syndromes follow.

Extramedullary Tumors

These tumors may be either intradural or extradural (epidural). They usually involve a few spinal cord levels and cause focal signs by compressing nerve roots, particularly the dorsal roots. Extramedullary tumors may ultimately affect the spinal cord, potentially progressing to complete loss of function below the level of the lesion. The first symptoms are typically focal pain and paresthesias, arising from pressure on the dorsal

a. Percentages may not add up to 100% due to rounding; b. Includes embryonal tumors, other tumors of the cranial and spinal nerves, other hematopoietic neoplasms, germ cell tumors, neoplasm unspecified; c. Includes diffuse astrocytoma, anaplastic astrocytoma and unique astrocytoma variants; d. Includes oligodendroglioma, anaplastic oligodendroglioma, oligoastrocytic tumors, glioma malignant, NOS, choroid plexus tumors, other neuroepithelial tumors and mixed neuronal-glial tumors. Abbreviatons: ICD, International Classification of Diseases; NOS, Not Otherwise Specified.

FIGURE 107.3 Distributions of primary spinal cord, spinal meninges, and cauda equina tumors by Central Brain Tumor Registry (CBTRUS) histology groupings and histology in children and adolescents (age 0-19 years, $N = 1,269$) **(A)** and adults (age 20+ years, $N = 17,479$) **(B)**, CBTRUS statistical report: National Program of Cancer Registries and Surveillance, Epidemiology, and End Results, 2011-2015. (From Ostrom QT, Gittleman H, Truitt G, Boscia A, Kruchko C, Barnholtz-Sloan JS. CBTRUS statistical report: primary brain and other central nervous system tumors diagnosed in the United States in 2011–2015. *Neuro Oncol.* 2018;20[suppl 4]:iv1-iv86.)

nerve roots. This symptom pattern is soon followed by sensory loss, weakness, and muscular wasting in the distribution of the affected roots. Compression of the spinal cord first interrupts the functions of the pathways that lie at the periphery of the spinal cord. The early signs of cord compression usually include those referable to upper motor neurons such as spastic weakness below the lesion, overactive tendon reflexes, and Babinski signs; impairment of cutaneous and proprioceptive sensation below the lesion; impaired control of the bladder and, less often, the rectum; and loss of superficial abdominal reflexes. Occasionally, symptoms may be those of lower motor neurons, such as underactive or absent reflexes with flaccid weakness, especially if the compression occurs abruptly as in spinal "shock" from trauma. If untreated, this syndrome may lead to signs and symptoms of complete transection of spinal cord, with wasting and atrophy of muscles at the level of the root lesion and, below the lesion, paraplegia or quadriplegia. The earliest and only sign can be pain, and the absence of other signs or symptoms may give the misleading impression that the cord is not compressed.

The severity and distribution of weakness and sensory loss varies, depending in part on the location of the tumor in relation to the anterior, lateral, or posterior portion of the spinal cord. Eccentrically placed tumors may cause a typical Brown-Séquard syndrome, namely, ipsilateral signs of posterior column and pyramidal tract dysfunction, with contralateral loss of pain and temperature due to involvement of the lateral spinothalamic tract. Usually, however, because of the external compression, the Brown-Séquard features are incomplete.

Spinal vessels may be occluded by extradural tumors, particularly metastatic carcinoma, lymphoma, or abscess. When the arteries destined for the spinal cord are occluded, the resulting myelomalacia causes signs and symptoms similar to those of a severe intradural process leading to necrosis of the spinal cord. Occlusion of major components of the anterior spinal artery, however, results in segmental lower motor neuron signs at the appropriate level, bilateral loss of pain and temperature sensation, and upper motor neuron signs below the lesion with preservation of dorsal column function (proprioception, discriminative tactile function, and vibration).

Extradural (Epidural) Tumors

Extradural lesions constitute the most frequent group of spinal tumors. Metastatic spinal disease accounts for 95% of those lesions, whereas primary bone tumors account for the remaining 5% of spinal lesions. In general, benign lesions within the vertebral bones are usually asymptomatic and found incidentally, whereas malignant vertebral tumors cause back pain, mechanical instability, pathologic fractures, and sometimes neurologic symptoms due to spinal cord compression. In addition to metastatic cancers, other malignant extradural tumors include multiple myeloma (Fig. 107.4), chordoma, Ewing sarcoma, and chondrosarcoma.

The most frequent benign bone lesions are hemangioma, enostosis, osteoid osteoma–osteoblastoma, aneurismal bone cyst, eosinophilic granuloma (histiocytosis), giant cell tumor, and osteochondroma. Although considered benign, these lesions can be locally aggressive associated with pain, spinal deformity, pathologic fractures, and neural elements compression. Spinal cord metastases are discussed in greater detail in the following section.

Epidural Spinal Cord Metastasis

Epidural spinal metastasis may be considered a disorder of the vertebral column; the neurologic consequences result from extension of tumor into the spinal canal. Although currently estimated to occur in about 5% to 10% of all cancer patients, as the survival of patients with systemic cancers improves, the incidence of epidural spinal cord compression has increased. Most studies have

FIGURE 107.4 Epidural spinal metastases. **A:** T2-weighted sagittal magnetic resonance imaging (MRI) demonstrates destruction and mild collapse of the T12 vertebra *(arrow)* in a patient with multiple myeloma. Note the hyperintense marrow signal at multiple levels in the spine indicating additional metastatic deposits. **B:** Axial T1 with contrast MRI at T12 level shows moderate canal stenosis *(arrow)*.

demonstrated that treatment of cord compression does not prolong survival, but prompt treatment may have an important palliative role, alleviating pain and preventing neurologic disability.

Signs and symptoms of epidural spinal cord compression can be overlooked in a patient with disseminated cancer because of the presence of diffuse pain and asthenia. However, persistent neck and back pain that typically gets worse at night or at rest should prompt an investigation, not waiting for neurologic dysfunction to ensue. Limb weakness or paresthesias in the distribution of a nerve root and bowel or bladder dysfunction make this a neurooncologic emergency that commands prompt evaluation and treatment. Rarely, aside from pain, the only manifestation of cord compression may be a gait disorder, often due to sensory ataxia, without overt evidence of weakness or cutaneous sensory loss. In this situation, it may even be difficult to demonstrate impaired proprioception. The ataxia may be caused by compression of spinocerebellar pathways. The primary malignancy in more than 50% of cases of epidural cord compression is lung (Fig. 107.5) or breast cancer. Overall, more than 80% of cases arise from primary tumors in lung, breast, prostate, gastrointestinal system, melanoma, or lymphoma.

The mechanism of spread of these tumors to the epidural space includes a direct extension from a paravertebral focus through a nerve root foramen, hematogenous metastasis to the vertebrae with extension from bone into the epidural space, or retrograde spread along the venous plexus of Batson. Hematogenous spread to bone is the most common form, and computed tomography (CT) typically shows lytic or blastic changes in the vertebral bodies in 85% of those patients. Osteoblastic changes are common with prostate carcinoma and are occasionally seen with breast cancer, whereas osteolytic changes are typically seen in multiple myeloma. The CT and magnetic resonance imaging (MRI) are sensitive techniques for the detection of spinal osseous metastases. Importantly, involvement of paraspinal lymph nodes with spread to the spinal canal is common

FIGURE 107.5 Epidural spinal metastases. Axial T1-weighted contrast-enhanced sequence at T5 demonstrates epidural extension of metastatic lung non–small cell carcinoma with bone destruction at this level.

with lymphoma. In this situation, the vertebral bone may be normal on imaging studies and use of screening spinal x-rays will be misleading.

Intradural Extramedullary Tumors

Neurofibromas, schwannomas, and meningiomas are the most commonly occurring primary intradural tumors of the spinal cord. On MRI with gadolinium, the lesions enhance brightly. Meningiomas may be identified by the presence of a dural tail, where the tumor attaches to the dura (Figs. 107.6 and 107.7).

A

B

FIGURE 107.6 Thoracic meningioma. **A:** T1-weighted contrast-enhanced sagittal magnetic resonance imaging (MRI) demonstrates a large intradural mass at T6-T7 with dural tail sign. **B:** Axial MRI demonstrates the large size of this lesion, probably a meningioma. Despite marked spinal cord compression, the patient had no abnormality on neurologic examination and only complained of left-sided thoracic pain.

FIGURE 107.7 Meningothelial meningioma of the spinal cord. The classic variant of meningioma is composed of lobules of meningothelial cells separated by fine collagen fibers. The intercellular borders are ill-defined characteristic of a syncytial pattern. Nuclear clearing and whorl formation are frequent. Calcifications (psammoma bodies) might be present. (Courtesy of Dr. Adriana Olar, Department of Pathology, MD Anderson Cancer Center.)

Symptoms may occur slowly, and some may be asymptomatic despite large size, presumably because of slow growth allowing the spinal cord an opportunity to adapt to the mass effect.

Leptomeningeal metastasis and drop metastases of intracranial tumors also involve the intradural space, but typically, they appear as small nodules attached to the surface of the cord or cauda equina nerve roots (Fig. 107.8), although many (approximately 70%) or not visible on imaging of brain or spine and are detected only by cerebrospinal fluid (CSF) analyses.

Intramedullary Tumors

Primary Intramedullary Tumors

The most common intramedullary tumors are ependymomas and astrocytomas. A diagnosis of von Hippel-Lindau syndrome, an autosomal dominant disorder, should be considered when a spinal hemangioblastoma is present (most commonly involving the thoracic cord) because this association occurs in one-third of the cases. However, rarely, hemangioblastoma can also occur in the intradural extramedullary and extradural locations. Although a single lesion is the most common presentation, multiple lesions occur in one-fifth of cases.

Primary intramedullary tumors usually extend over many segments, causing dilatation of the spinal cord and sometimes causing syringomyelia, which can involve the whole length of the spinal cord. For this reason, the signs and symptoms of intramedullary tumors are more variable than those of extramedullary tumors (Figs. 107.9 and 107.10).

If the tumor is restricted to one or two segments, the clinical presentation can be similar to that of an extramedullary tumor. Pain may be an early manifestation if the dorsal root entry zone is affected. Compression of the crossing pain fibers in the central cord may cause loss of pain and temperature only in the affected segments. As the tumor spreads peripherally, the spinothalamic tracts may be affected; in the thoracic and cervical areas, pain and temperature fibers from the sacral area lie near the external surface of the cord and may be spared (eg, sacral sparing). Involvement of the central gray matter destroys the anterior horn

FIGURE 107.8 Leptomeningeal disease. Sagittal T1-weighted contrast-enhanced magnetic resonance imaging shows tumor deposits along the surface of the distal thoracic cord and the nerve roots of the cauda equine in a patient with breast carcinoma.

cells, with local weakness and atrophy resulting. However, pyramidal fibers may be spared. The clinical picture may be identical to that of syringomyelia with a "suspended" sensory level.

Intramedullary Metastases

Although rare, the most common tumors that cause intramedullary metastases are lung cancer or breast cancer. Intramedullary metastases typically occur with advanced metastatic disease, and at autopsy, 61% of patients with intramedullary metastases are found to have had multiple sites of cerebral or spinal lesions. Contrast-enhanced MRI is the preferred method for detection of intramedullary metastases. Reversal or stabilization of neurologic signs depends on early diagnosis, but survival is poor; 80% of patients in one series died within 3 months of diagnosis, likely a manifestation of the extent of systemic disease at the time of the spinal cord involvement.

Regional Syndromes

Foramen Magnum Tumors

Tumors in the region of the foramen magnum may extend up into the posterior fossa or down into the cervical region. The syndrome from tumor in the foramen magnum typically shows signs and symptoms of dysfunction of the lower cranial nerves, primarily those pertaining to the 11th, 12th, and rarely, the 9th and 10th. The most characteristic foramen magnum tumor, the ventrolateral meningioma, compresses the spinal cord at the cervicomedullary junction to cause long tract signs: loss of position, vibratory, and light touch perception, with more prominent symptoms in the arms than the legs. Upper motor neuron signs are seen in all four limbs. There may be cutaneous sensory loss in distribution of C2 or the occiput, with posterior cranial headaches and high cervical pain. Progression of sensory and motor symptoms may involve the limbs asymmetrically.

Cervical Tumors

Tumors of the upper cervical segments cause pain or paresthesias in the occipital or cervical region, with stiff neck, weakness, and wasting of neck muscles. Below the lesion, there may be a

FIGURE 107.9 Intramedullary glioblastoma. **A:** Sagittal T1-weighted contrast-enhanced magnetic resonance imaging (MRI) demonstrates T1-T4 intramedullary lesion with peripheral enhancement and hypointense center that expands the cord. **B:** T1-weighted MRI shows a contrast-enhancing intramedullary tumor at the T1-T2 level. At operation, a spinal glioblastoma with necrotic center was removed.

FIGURE 107.10 Intramedullary ependymoma. **A:** Sagittal T1-weighted magnetic resonance imaging shows an intramedullary enhancing mass at C5-T1. **B:** Axial T1-weighted image with contrast shows expansion and significant displacement of the cord by the tumor at C6 *(arrow)*.

spastic tetraplegia or hemiplegia. Cutaneous sensation may be affected below the lesion, and the descending trigeminal nucleus may be involved. Characteristic findings make it possible to localize the upper level of spinal tumors in the middle and lower cervical segments or T1 as shown in Table 107.1.

Other signs of cervical tumors include nystagmus, which is attributed to involvement of the descending portion of the median longitudinal fasciculus. A Horner syndrome may be found with intramedullary lesions in any portion of the cervical cord if the descending sympathetic pathways are affected.

TABLE 107.1 Localization in the Cervical and T1 Region Based on Symptomatology

C4	Paralysis of the diaphragm
C5	Atrophy and paralysis of the deltoid, biceps, supinator longus, rhomboid, and spinati muscles. The upper arms hang limp at the side. The sensory level extends to the outer surface of the arm. The biceps and supinator reflexes are lost.
C6	Paralysis of triceps and wrist extensors. The forearm is held semiflexed, and there is a partial wrist drop. The triceps reflex is lost. Sensory impairment extends to a line running down the middle of the arm slightly to the radial side.
C7	Paralysis of the flexors of the wrist and of the flexors and extensors of the fingers. Efforts to close the hands result in extension of the wrist and slight flexion of the fingers (eg, preacher's hand). The sensory level is similar to that of the sixth cervical segment but slightly more to the ulnar side of the arm.
C8	Atrophy and paralysis of the small muscles of the hand with resulting claw hand (main-en-griffe). Horner syndrome, unilateral or bilateral, results from lesions at this level and is characterized by the triad of ptosis, small pupil (ie, miosis), and loss of sweating on the face. Sensory loss extends to the inner aspect of the arm and involves the fourth and fifth fingers and the ulnar aspect of the middle finger.
T1	Lesions rarely cause motor symptoms because the T1 nerve root normally provides little functional innervation of the small hand muscles.

Thoracic Tumors

Clinical localization of tumors in the thoracic region of the cord is best made by the sensory level. It is not possible to determine the location of a lesion in the upper half of the thoracic cord by testing the strength of intercostal muscles. Lesions that affect the abdominal muscles below T10 but spare the upper ones may be localized by the Beevor sign (ie, the umbilicus moves upward when the patient, lying in the supine position, attempts to flex the neck against resistance). Abdominal skin reflexes are absent below the lesion.

Lumbar Tumors

Lesions in the lumbar region may be localized by the level of the sensory loss and motor weakness typically following a dermatome or myotome distribution. Tumors that compress only the L1 and L2 nerve roots cause loss of the cremasteric reflexes and weakness in the iliopsoas muscle. The abdominal reflexes are preserved, as are the knee and ankle jerks. Lesions affecting the L3 and L4 nerve roots may present with weakness in the quadriceps muscle, loss of patellar reflex, and pain in the anteromedial portion of the lower extremity.

The typical involvement of the L5 nerve root causes weakness of eversion, inversion, and dorsiflexion of the foot and hallux. Decreased sensation over the anterolateral calf and dorsum of the foot, with pain radiating down the leg to the hallux that can be exacerbated by the straight leg testing (Lasègue sign) is also characteristic. The presence of weakness of foot inversion in an L5 radiculopathy is an important distinguishing factor from a peroneal palsy where foot inversion strength is typically normal.

A tumor affecting the S1 root may present with weakness of the gastrocnemius and hamstring, with absent ankle jerk and decreased sensation over the lateral calf and lateral foot including the sole.

The involvement of multiple nerve roots can occur at any lumbar level, and it is usually described as cauda equina syndrome, which typically presents as flaccid paralysis of the legs with loss of knee and ankle reflexes associated with urinary retention and bowel incontinence. If both the spinal cord and cauda equina are asymmetrically affected, there may be spastic paralysis of one leg with an overactive ankle reflex on that side and flaccid paralysis with loss of reflexes on the other side.

Finally, tumors affecting the sacrum at the level of S2-S4 can cause perineal or saddle anesthesia and loss of bowel and bladder control without motor deficits observable in the lower extremities because the motor roots (L1-S1) are not affected.

Tumors of the Conus and Cauda Equina

Although a conus lesion is intramedullary involving the parenchyma of the terminal spinal cord, a cauda equina lesion is extramedullary affecting multiple exiting nerve roots. Distinguishing between the two entities is not always possible as many of the clinical features are similar. Moreover, in neoplastic processes, there is frequent involvement of both.

The first symptom of a tumor that involves the conus or cauda equina is pain in the back, rectal area, or both lower legs, often leading to the preliminary diagnosis of sciatica. Loss of bladder function and impotence are seen early especially with conus involvement. As the tumor grows, there may be flaccid paralysis of the legs, with atrophy of leg muscles, and foot drop. Fasciculation may be evident. Sensory loss may affect the perianal or saddle area and the remaining sacral and lumbar dermatomes. This loss may be slight or so severe that a trophic ulcer develops over the lumbosacral region, buttocks, hips, or heels.

DIAGNOSIS

Spinal tumors must be differentiated from other disorders of the spinal cord, including transverse myelitis, multiple sclerosis, syringomyelia, combined system disease, syphilis, amyotrophic lateral sclerosis, anomalies of the cervical spine and base of the skull, spondylosis, adhesive arachnoiditis, radiculitis of the cauda equina, hypertrophic arthritis, ruptured intervertebral disks, diastematomyelia, and vascular anomalies.

Multiple sclerosis, with a complete or an incomplete transverse lesion of the cord, may usually be differentiated from spinal cord tumors by the remitting course, signs and symptoms of more than one lesion, evoked potential studies, cranial MRI, and the presence of CSF oligoclonal bands. Acute transverse myelitis may occasionally enlarge the cord to simulate an intramedullary tumor.

Determining the differential diagnosis between spontaneous syringomyelia and intramedullary tumor-related syrinx is complicated because intramedullary cysts mimicking a syrinx are commonly associated with these tumors. Extramedullary tumors in the cervical region may give rise to localized pain and muscular atrophy in conjunction with a Brown-Séquard syndrome, producing a clinical picture similar to that of syringomyelia. The differential diagnosis may often be made by contrast-enhanced MRI that reveals a tumor nodule.

The combination of atrophy of hand muscles and spastic weakness in the legs in amyotrophic lateral sclerosis may suggest the diagnosis of a cervical cord tumor. Tumor is excluded by the lack of paresthesias, and normal sensation on examination, and by the presence of fasciculation or atrophy in leg muscles or tongue, and by imaging.

Cervical spondylosis may cause stenosis of the spinal canal and cause symptoms and signs of root irritation and/or compression of the spinal cord. Degenerative changes are extremely common, and the modality of choice for diagnosis is MRI. Clinical correlation with image findings is critical for the treatment decision because most changes on imaging studies are incidental findings or do not have a clinical correlation.

Anomalies in the cervical region or at the base of the skull, such as platybasia or Klippel-Feil syndrome, are diagnosed by CT or MRI. Occasionally, arachnoiditis may interfere with the circulation of CSF causing signs and symptoms of a transverse lesion. The CSF protein content is usually elevated. Diagnosis is made by complete or partial arrest of the contrast column on myelography or by fragmentation of the material at the site of the lesion. Slowed CSF flow will be seen using magnetic resonance flow techniques.

Epidural lipomatosis is a complication of prolonged steroid therapy but sometimes occurs without apparent cause; the fat accumulations act as an extradural mass lesion, causing low back pain and compression of the spinal cord or cauda equina.

Radiography

The diagnosis of an intraspinal tumor may be established before the operative procedure, with visualization by CT, MRI, or myelography. Vascular malformations or vascular tumors may be best visualized by spinal angiography. A CSF examination with cytologic studies may also be helpful if positive, but negative cytology does not exclude a neoplastic process.

The CT and MRI have replaced standard radiographic studies (plain x-rays). However, when conventional x-ray imaging is performed, the abnormalities (listed in the following text) are seen in about 15% of spinal neoplasms:

1. Localized destruction of the vertebrae is manifest by scalloping of the posterior margin of the vertebral body or lucency of a portion of the vertebra or pedicle.
2. Changes occur in the contour or separation of the pedicles (eg, the interpediculate distance may be measured and compared with normal values). Localized enlargement of foramina is seen with dumbbell neurofibromas. Localized enlargement of the spinal canal is usually diagnostic of an intraspinal tumor, but enlargement of many segments may be a developmental anomaly.
3. Paraspinal tissues are distorted by tumors, frequently neurofibromas that extend through the intervertebral foramen or by tumors that originate in the paraspinal structures.
4. Proliferation of bone, which is rare except in osteomas and sarcomas, is also occasionally seen in hemangiomas of bone and meninges.
5. Calcium deposits are occasionally present in meningiomas or congenital tumors.

An MRI has largely supplanted myelography for imaging both intramedullary and extramedullary processes. The MRI is the most useful test for evaluating spinal tumors. The vertebral bodies, spinal canal, and spinal cord, itself, are clearly delineated. Most spinal neoplasms display contrast enhancement. When a metastatic tumor is suspected or demonstrated, it is advisable to image the entire spinal cord because more than one lesion may be present.

The CT is the modality of choice for imaging of the bony structures but is more limited than MRI in demonstrating the soft tissues. Injection of contrast in the lumbar cistern is used for a CT myelogram, which is an alternative in cases of contraindication for MRI (ie, pacemakers or ferromagnetic implants).

A CT myelogram may demonstrate the soft-tissue changes of intraspinal tumors and is particularly useful in the diagnosis of cystic lesions in the subarachnoid space, where the contrast material may accumulate around and create a negative contrast of the cyst. It is also useful to evaluate if there is communication between the subarachnoid space and intradural cystic lesions (ie, arachnoid cysts, syringomyelia, or cystic tumors).

Cerebrospinal Fluid

When there is a complete subarachnoid block, the CSF is xanthochromic as a result of the high protein content (Froin syndrome). It may be only slightly yellow or even colorless if the subarachnoid block is incomplete. The cell count is usually normal, but a slight pleocytosis is found in about 30% of patients. Cell counts of between 25 and 100/μL are found in about 15% of patients. The protein content is increased in more than 95%. Values of over 100 mg/dL are present in 60% of the patients, and values of over 1,000 mg/dL are present in 5% and may, in rare cases, lead to communicating hydrocephalus. The glucose content is normal unless there is meningeal spread. Cytologic evaluation of the CSF is useful when malignant tumors are suspected, although, as mentioned previously, negative cytology does not exclude leptomeningeal cancer. More than one CSF sampling procedure may be required (some advocate up to five), although the remainder of the CSF profile (cells, protein, tumor markers) is usually abnormal in the setting of leptomeningeal metastases, notwithstanding the absence of malignant cells on cytologic analysis.

MANAGEMENT

Intradural Extramedullary Tumors

Once the diagnosis of an intraspinal tumor has been made, the treatment is surgical removal of the tumor whenever possible. When the neurologic disorder is severe or rapidly progressing, emergency surgery is indicated. The best results are obtained when the signs and symptoms are due solely to compression by a benign encapsulated extramedullary tumor. Some of these tumors, especially meningiomas, may lie anterior to the spinal cord, and a complete resection of the involved dura is not possible or carries a significant risk of morbidity. In these cases, a gross total resection of the mass with cauterization of the dural insertion of tumor is performed. In cases of recurrence, another surgical resection may be necessary. The functional outcome of patients harboring extramedullary tumors is predicated by the severity of the preoperative neurologic disability. Overall, surgery aiming at a gross total resection is the modality of choice for the intradural extramedullary tumors (Video 107.1) and ideally should be performed before installment of neurologic dysfunction because when this occurs, it might represent evidence of irreversible damage to the spinal cord due to compression or ischemia. Radiotherapy is typically not indicated for benign intradural extramedullary tumors. In fact, most of these lesions are low-grade tumors with no tissue separation between the lesion and the spinal cord. This increases the risk of radiation-induced myelopathy, especially in cases where preexisting damage is suspected (ie, evidence of myelomalacia or ischemia due to long-dated compression). In cases of recurrence, a second surgical procedure is usually considered a better alternative than radiation, which in general is reserved for cases where a high surgical comorbidity precludes surgery.

Intramedullary Tumors

In almost all World Health Organization (WHO) grade I (myxopapillary) and WHO grade II ependymomas, complete microsurgical resection of the tumor is the treatment of choice (Video 107.2). There is no consensus on the use of radiotherapy for WHO grade I and WHO grade II spinal cord tumors, and overall radiation is reserved for cases with incomplete resection, with bulky residual disease or symptomatic tumor recurrence when the patient is considered not to be a good surgical candidate. Radiation treatment is indicated after initial surgery for all patients with WHO grade III ependymoma. Treatment paradigms might change over the coming years with recent identification of discrete molecular ependymoma subtypes. Astrocytomas are typically infiltrating and often lack a plane of cleavage. In this case, an attempt at complete resection or extensive debulking is associated with significant risk of neurologic decline. Although radiotherapy should be given for spinal cord astrocytomas, the results particularly for WHO grade III and IV tumors are discouraging. For other less common intramedullary tumors, such as hemangioblastomas, teratomas, or dermoids, if complete removal has been achieved, typically, no further treatment is recommended aside from surveillance.

Intramedullary tumors are typically approached with multilevel laminectomies, which create disruption in the posterior tension band of the ligaments stabilizing the spine. As a result, spinal deformities that may have been present preoperatively may worsen and other deformities may develop, eventually requiring surgical correction with spinal instrumentation and fusion. If allowed to progress, these deformities may create additional functional impairment, especially in skeletally immature patients. Some surgeons have advocated replacement of the lamina after definitive surgery, rather than the standard laminectomy. However, the occurrence of postoperative kyphosis is common and the natural history of this deformity is uncertain. The additional use of radiotherapy for intraspinal tumors in younger patients may affect the growth of the spine and in adults may increase the muscle atrophy and degenerative changes leading to the development or worsening of preexisting deformities of the spine.

Epidural Disease From Metastatic Cancer

Treatment of epidural metastasis is palliative in nearly all patients. Prognostic scoring systems based on patient age, performance status, extent of spinal and extraspinal disease, tumor histology, and availability of systemic treatments are useful to predict the expected survival of patients harboring spinal metastasis. However, management has to be individualized in order to achieve the best balance between morbidity and palliation. A randomized trial LEVEL I[1] has demonstrated that surgery for spinal decompression and spinal stabilization followed by radiation is superior to conventional radiation alone in maintenance and recovery of ambulation, duration of ambulation, and maintenance of sphincter continence. Loss of bowel or bladder function is an ominous prognostic sign and is usually irreversible. Among patients diagnosed and treated early, 94% remain ambulatory until they die.

Conventional radiation therapy is the mainstay of treatment for most patients with spinal metastases, even those who had surgical decompression, with the typical treatment plan comprising 3,000 cGy divided in 10 fractions of 300 cGy each. More recently, high-dose hypofractionated radiotherapy using image-guided techniques (spinal stereotactic radiotherapy) has emerged

as an effective modality overcoming the relative radioresistance of some tumors to conventional radiation. However, in cases of symptomatic or high-degree spinal cord compression, a judicious combination of surgery to separate the tumor from the spinal cord prior to stereotactic radiation has been shown to achieve a high degree of local control with relative low morbidity.

In general, surgery provides spinal stabilization and spinal cord and nerve roots decompression, whereas radiation therapy provides local tumor control. Usually, radiation treatment is well tolerated even by patients who are seriously ill, and in most cases, palliation is often achieved with relief of pain. In general, indications for surgery include spinal cord compression due to radioresistant tumors (renal cell carcinoma, sarcomas, melanomas, etc), spinal instability, unknown tissue diagnosis, or rapid progression of neurologic dysfunction. Judicious use of surgery is critical to achieve a meaningful clinical improvement in patients with advanced systemic disease because the anticipated recovery time has to be weighed against the expected duration of survival.

OUTCOME

Epidural spinal cord compression is an emergency because without treatment, irreversible loss of neurologic function will lead to significant morbidity and mortality. It is estimated that patients who were ambulatory preoperatively were 2.3 times more likely to be able to walk postoperatively. Treatment should be initiated early, as neurologic status at presentation is predictive of functional outcome. Critical to this is the education of patients, patient families, and health care providers to recognize warning signs of cord compression early on. Recent studies do support the notion that patients with cord compression are presenting earlier. In fact, although a study published in 1998 showed that only 33% were ambulatory and 53% were catheter free at the time of initiation of therapy, in another study published in 2010, 62% of patients were ambulatory at presentation. It has also been shown that nonambulatory patients if treated surgically require more extensive surgery with consequent higher complication rates and morbidity. It is therefore of paramount importance that a careful patient selection process is pursued, always taking into consideration the patient's overall prognosis and presumed benefits balanced against the treatment-related morbidity.

For intramedullary tumors, the prognosis and outcome from surgery is strongly related to tumor histology and the occurrence of a plane of surgical dissection between the lesion and the surrounding spinal cord and nerve roots. When a plane of cleavage exists, such as in ependymomas, a complete surgical resection is potentially curative. With more diffusely infiltrating tumors such as spinal cord astrocytic tumors, the goal of surgery in most cases is diagnostic and especially in high-grade tumors, treatment is palliative with a dismal outcome irrespective of treatment.

Overall, intradural extramedullary tumors have slow progression, and usually, treatment is recommended when symptomatic or when there is a significant degree of spinal cord compression. With improved imaging, neurophysiologic monitoring, and sound microsurgical techniques, the goals of treatment for these lesions is gross total resection with curative intent. Good functional outcomes are generally observed and overall recurrence rates range between 0% and 13%.

This is in contrast to the prognosis of patients with leptomeningeal metastasis from systemic cancer where the prognosis, irrespective of the cancer of origin, is typically around 2 to 3 months, although there are exceptions, most often patients with lymphoma and occasionally breast cancer.

Paraneoplastic Syndromes 108

Erika Santos Horta and Tobias Walbert

KEY POINTS

1. Paraneoplastic syndromes have a broad spectrum of symptoms.
2. There is no one-to-one relation between a symptom and an antibody. Therefore, a panel of antibodies needs to be tested.
3. Paraneoplastic syndromes are treatable if quickly recognized. Usually, they are the first symptom of an undiagnosed cancer.
4. Pathogenic antibodies target a synapse protein or a membrane channel.
5. Antibodies targeting nuclear or cytoplasmic proteins are markers of the disease and highly associated with cancers.
6. Management includes diagnosis of the syndromes, the antibody or antibodies associated, a malignancy workup, and treatment.

INTRODUCTION

Paraneoplastic syndromes are a group of disorders that share common neurologic symptoms and an antibody. The neurologic manifestations are broad and include central nervous system and peripheral nervous system disorders. The spectrum of neurologic manifestations is outlined in Figure 108.1.

An association with cancer is not always confirmed but common. When associated with malignancy, paraneoplastic syndrome is called *classic* paraneoplastic syndrome. Although there is no one-to-one association among antibody, clinical manifestation and cancer, Table 108.1 summarizes the most common antibodies and paraneoplastic diseases, and the cancers most often associated with them.

FIGURE 108.1 Summary of manifestations of paraneoplastic syndromes.

In 1976, Purkinje cell cytoplasmic antibody–Tr (PCA-Tr) was found in a patient with Hodgkin lymphoma who developed acute cerebellar degeneration, this was the first instance that an antibody was associated with a neurologic symptom. Since then, the number of antibodies associated with neurologic paraneoplastic disorders has increased to over 30 recognized antibodies.

The knowledge of paraneoplastic syndromes is important because these disorders are treatable and might be the first symptom of an undiagnosed cancer.

EPIDEMIOLOGY

Paraneoplastic syndromes are seen in less than 1% of cancer patients. On the other hand, it is a diagnosis to be highly considered in some selected phenotypes. For example, paraneoplastic encephalitis is the cause of 7.5% of encephalitis cases in the United Kingdom.

Paraneoplastic syndromes affect patients of any age, from children to the elderly. Although some antibodies are highly associated with gender, like Purkinje cell cytoplasmic antibody type 1 (PCA-1) and *N*-methyl-D-aspartate (NMDA) receptor antibody with women and anti-Ta with men, paraneoplastic syndromes as an entity do not have a gender bias.

PATHOBIOLOGY

Although cancer attempts to evade the immune system, cancerous cells do express proteins, including intracellular ones. These proteins become antigens and are recognized by systemic antibodies. Paraneoplastic diseases happen when these antibodies recognize proteins that are also expressed by cells in the nervous system. Therefore, paraneoplastic syndromes are an intersection of neuroimmunology and neurooncology.

Antibodies can be pathogenic or markers of the paraneoplastic syndrome. Pathogenic antibodies such as voltage-gated potassium membrane complex (VGKC) and NMDA antibodies, usually target a synapse protein or a membrane channel. Antibodies that target nuclear or cytoplasmic proteins are usually markers of the disease and cluster of differentiation 8-T-cell receptor (CD8-T) are the cells driving the pathologic process. Examples of this class are PCA-1 and antineuronal nuclear antibody type 1 (ANNA-1).

Interestingly, cancers are more commonly associated with antibodies that target intracellular proteins than with those targeting a membrane complex or protein.

Neuroaxonal swelling, neuronal loss, chromatolysis, vacuolization of neurons, microglial proliferation, and infiltration of T cells are seen microscopically.

TABLE 108.1 Paraneoplastic Syndromes, Associated Cancers, and Antibodies

Syndrome	Frequent Associated Tumors	Frequent Associated Antibodies
Encephalitis	Lung, testicular, ovarian teratoma, thymoma, breast	ANNA-1 (Anti-Hu), NMDA, VGKC, CRMP5 (CV2), amphiphysin, Ta (Ma2), AMPA, $GABA_B$
Epilepsy	Thymoma, lung	VGKC, GAD65, CRMP5
Myelitis	Lung, breast, kidney, thyroid, ovarian endometrium, melanoma	Amphiphysin, CRMP5, PCA-1 (Anti-Yo), ANNA-1 (anti-Hu), ANNA-2, ANNA-3, AQP4, GFAP
Cerebellar degeneration	Ovarian, breast, lung, Hodgkin lymphoma	PCA-1 (Anti-Yo), PCA-2, PCA-Tr, ANNA-2, ANNA-1 (anti-Hu), CV2/CRMP5, GAD65
Peripheral neuropathy/ neuronopathy/autonomic	Lung, breast	ANNA-1, CV2/CRMP5, VGKC, peripherin, gACH, DPPX
Movement disorders	Neuroblastoma, lung, breast cancer, ovarian cancer	ANNA-1, ANNA-2, NMDA, CRMP5, Ta/Ma2
Stiff-person syndrome	SCLC, breast cancer, thymoma, Hodgkin lymphoma, adenocarcinoma	GAD65, amphiphysin, ANNA-2 (Anti-Ri), GlyR
LEMS	Thymoma, lung	VGCC, SOX1
Myasthenia Gravis	Thymoma, lung	mACHR, STR
Retinopathies	SCLC, melanoma	Antirecoverin, antiretinal bipolar cell, CV2/CRMP5

Abbreviations: AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic; ANNA, antineuronal nuclear antibody; AQP4, aquaporin-4; CRMP5, collapsin response mediator protein 5; DPPX, dipeptidyl-peptidase-like protein 6; $GABA_B$, γ-aminobutyric acid type B; gACH, ganglionic acetylcholine receptor; GAD65, glutamic acid decarboxylase 65; GFAP, glial fibrillary acidic protein; GlyR, glycine receptor; LEMS, Lambert-Eaton myasthenic syndrome; mACHR, muscarinic acetylcholine receptor; NMDA, *N*-methyl-D-aspartate receptor; PCA, Purkinje cell cytoplasmic antibody; SCLC, small cell lung cancer; SOX1, SRY-related HMG-box genes; STR, striational; VGCC, voltage-gated calcium channel; VGKC, voltage-gated potassium membrane complex.

CLINICAL MANIFESTATIONS

It is important to understand that paraneoplastic disease phenotypes are not necessarily distinct from each other. Patients with the same antibody can present with different manifestations. Furthermore, a patient with one antibody can present with a combination of symptoms like limbic encephalitis and seizures or with an encephalomyelopathy.

Encephalitis

Encephalitis is the most common central nervous system manifestation of paraneoplastic disease. The majority of antibodies have been associated with encephalitis, including ANNA-1 and γ-aminobutyric acid antibodies. Acute/subacute limbic and/or brainstem encephalitis presents with memory loss and confusion and is usually associated with other symptoms like seizures or psychiatric symptoms. This condition can antedate the diagnosis of cancer for about 6 months.

NMDA antibody is the most common antibody found in paraneoplastic encephalitis. Some characteristics of NMDA-antibody encephalitis are extreme delta brush in electroencephalogram, movement disorders symptoms like chorea and jaw dystonia, autonomic disability, and breathing instability. Ovarian teratoma is the classic tumor associated with this antibody. Recently, cases of this entity have been seen after viral infections, especially herpes simplex encephalitis.

Ta antibody, also known as *Ma2 antibody*, is usually seen in young men and associated with testicular cancer; however, Ma1 antibody can be seen in both genders. Both Ma1 and Ma2 antibodies cause encephalitis with memory and behavior alteration as well as ophthalmology features, including opsoclonus and ophthalmoplegia.

VGKC antibody includes all the antibodies against elements of the VGKC-membrane complex, like LGI1 and Caspr2. It can mimic or come with Creutzfeldt-Jakob disease. Interestingly, hyponatremia is a common finding in patients with LGI1-antibody encephalitis.

Epilepsy

Epilepsy related to paraneoplastic antibodies presents as new onset, within months of partial or secondary generalized seizures. They are difficult to treat solely with antiseizure medications. The most frequent type is temporal lobe epilepsy. Other common neurologic manifestations are encephalitis and cognition deficits as well as behavioral changes and movement disorders. The most common antibodies identified are VGKC, mainly LGI1 subtype, glutamic acid decarboxylase 65 (GAD65), and collapsin response mediator protein 5 (CRMP5) antibodies.

LGI1 antibody can have a distinct manifestation of brief dystonic movements of the face and ipsilateral arm called *faciobrachial seizures*. If not treated with immunotherapy, this progresses to encephalitis and temporal lobe epilepsy.

Myelitis

Myelitis is usually associated with encephalopathy and therefore presents as an encephalomyelopathy. The course of the disease is subacute and progressive. It can precede the diagnosis of cancer for up to 18 months. Multiple antibodies such as amphiphysin, anti–ANNA-1 and ANNA-2, CRMP5, and even aquaporin-4 (AQP4) antibodies have been associated with paraneoplastic myelitis.

A new antibody associated with myelitis is glial fibrillary acidic protein antibody. Myelitis is usually central and longitudinally extensive with contrast enhancement. Magnetic resonance imaging (MRI) of the brain can show a peculiar pattern of radial periventricular enhancement, as lines coming from the

ventricle to the cortex. Common associated symptoms are headaches, vision distortions, and tremors.

Cerebellar Ataxia

Cerebellar ataxia is caused by immunologic attack to the Purkinje cells in the cerebellum. It usually starts with gait ataxia that within weeks progresses to trunk and limbs followed by dysarthria, nystagmus, vertigo, and diplopia. It is so aggressive that patients can be bed bound over the course of months. Antibodies associated with this syndrome are PCA-1, PCA type 2, PCA-Tr, and also GAD65 and amphiphysin antibodies. The most common cancers linked with cerebellar ataxia are ovarian, breast, small cell lung cancer, and Hodgkin lymphoma.

Neuropathies

Although this chapter focuses on the association of paraneoplastic disease with antibodies, it does not cover any polyneuropathy, organomegaly, endocrinopathy, M components, and skin changes or monoclonal gammopathy of unclear significance. Paraneoplastic neuropathies, as with other paraneoplastic syndromes, usually predate a cancer diagnosis.

Sensory Neuronopathy

Sensory neuronopathy occurs due to an immunologic attack to the dorsal root ganglion. The loss of proprioception causes ataxia. This presentation is highly associated with cancer, and over 70% of patients have small cell lung cancer. It usually presents over the course of weeks, usually affecting arms first. It is asymmetrically progressive to the point that the patient becomes bedbound. The most common antibody is ANNA-1 antibody, followed by amphiphysin and CRMP5 antibodies.

Sensory-Motor Neuropathies

The neuropathies can be axonal, demyelinating, or vasculitic. The patient's history, electroneuromyography, or biopsy will not differentiate between a paraneoplastic or nonparaneoplastic neuropathy. Therefore, the only possibility of correct diagnosis is to order a paraneoplastic panel. ANNA-1 and CRMP5 are common antibodies. Pain can be a symptom of neuropathy caused by VGKC and CRMP5 antibodies. An acute form of neuropathy that resembles Guillain-Barré syndrome can be found with ANNA-1 antibody.

Autonomic Neuropathies

Autonomic neuropathies are due to immune attack to the autonomic ganglia. The spectrum of autonomic symptoms is broad, including orthostatic hypotension, sweat abnormalities, and gastric dysmotility or pseudo-obstruction. The gastric dysmotility is caused by immune attachment to the enteric neurons. The most common antibody is ganglionic acetylcholine receptor (gACH), but it can also be seen with CRMP5, peripherin, and dipeptidyl peptidase-like protein 6 antibodies. gACH-antibody positivity was identified in 16% of patients with dysautonomia, and although not found in other paraneoplastic syndromes, gACH-antibody levels correlate with severity of autonomic dysfunction.

Motor Neuropathies

These are extremely rare, and case reports are seen in patients with small cell lung cancer. Antibodies associated with motor neuropathies are ANNA-1 and CRMP5 antibodies.

Peripheral Hyperexcitability

Neuromyotonia is characterized by spontaneous and continuous muscle activity with delayed relaxation due to hyperexcitability of peripheral nerves. Clinically, muscle twitching is seen because the patient complains about muscle stiffness.

Morvan syndrome is characterized by neuromyotonia, encephalopathy as neuropsychiatric features, dysautonomia, and neuropathic pain. VGKC antibodies (specially anti-Caspr) are often associated with this syndrome, and it is linked with thymoma.

Isaac syndrome is another hyperexcitability syndrome associated with VGKC-complex antibodies and neuromyotonia. Different from Morvan syndrome, cramps are common and it does not have central nervous manifestations.

Neuromuscular Junction Disorders

Paraneoplastic neuromuscular junction disorders are Lambert-Eaton myasthenic syndrome (LEMS) and myasthenia gravis (MG).

LEMS is caused by antibody attack to the voltage-gated calcium channel (VGCC) receptor. Symptoms are muscle weakness that can be accompanied by dysautonomia. Improvement of reflexes and strength after exercise can be seen in neurologic exam. Electroneuromyography shows improvement of the compound muscle action potential with high-frequency nerve stimulation or after sustained isometric muscle contraction. Positivity for VGCC antibody plus another antibody is highly predictive of cancer. For example, lung cancer was found in 70% of patients with positivity for antibodies against VGCC N-type and p/q type channels and SOX1 antibodies.

MG is characterized by fluctuating weakness that not only affects voluntary muscles like eyes but also cause respiratory insufficiency. Electroneuromyography is the gold standard to diagnose the condition and it shows decrease of the compound muscle action potentials after high-frequency stimulation or after sustained isometric muscle contraction. It is estimated that MG will manifest in 40% of patients with thymoma (Vernino, Lennon 2004), and in this case, besides muscarinic acetylcholine receptor–antibody positivity, it demonstrates positivity for other antibodies. In patients that tested positive for muscarinic acetylcholine receptor and striational antibodies, plus CRMP5 or VGKC antibody, cancer was diagnosed in 81% and of those, 85% had thymoma.

Myopathy

Paraneoplastic myositis is largely represented by dermatomyositis and polymyositis. These conditions are beyond the scope of this chapter and are discussed in detail in Chapter 94. Autoimmune necrotizing myopathy can be seen with signal recognition particle antibody. There are rare cases of patients with ANNA-1 antibody presenting with myopathy.

Movement Disorders

Many paraneoplastic antibodies can cause hypokinetic or hyperkinetic movement disorders. Eighty percent of patients with the NMDA antibody have orobuccolingual movements and/or chorea. Chorea is also seen with CRMP5 and ANNA-1 antibodies. Myoclonus can be seen with ANNA-1 and VGKC-complex antibodies, especially with the LGI1 antibody. Jaw dystonia is associated with the ANNA-2 antibody. Parkinsonism can be seen with Ta/Ma2, ANNA-2, and LGI1 antibodies.

Stiff-person syndrome is represented by muscle rigidity and painful spasms. When combined with encephalomyelitis and dysautonomia the condition is called *progressive encephalomyelitis*. The most common antibody found in these patients is anti-GAD65, but amphiphysin and glycine receptor antibodies are also found.

Paraneoplastic Disorders Affecting the Eyes

The spectrum of eye involvement in paraneoplastic disorders is broad, including neuritis, cranial nerve neuropathies, and eye movement disorders such as nystagmus.

Paraneoplastic optic neuritis is characterized by the sudden painless onset of central scotoma. It is usually bilateral with swelling of the optic discs and altered visual-evoked potential. Paraneoplastic optic neuritis is seen with CRMP5 and ANNA-1 antibodies as in cases of paraneoplastic optic neuromyelitis with aquaporin-4 antibody

Cancer-associated retinopathy is usually also bilateral and painless. Photopsias are present, such as night blindness, constriction of the visual field, and central scotomas. On examination, arteriolar narrowing can be observed as with optic disc pallor. Electroretinography, optical coherence tomography, and fluorescein angiography do not show any alterations specific to paraneoplastic retinopathy. The most common cancer is small cell lung cancer, but cases with prostate, colon, and breast cancer have also been observed. The classic recoverin antibodies are only seen in a small number of patients, but tests should be performed for other antibodies that can damage retinal proteins. The most common is α-enolase antibody. Melanoma-associated retinopathy has rapid onset of mild loss of visual acuity and photopsias such as scotomas. In this case, antibodies are against retinal bipolar cells.

Opsoclonus-myoclonus is usually associated with ANNA antibodies. In children, neuroblastoma should be ruled out. In adults, tumors associated with this syndrome are small cell lung cancer as well as breast and other gynecologic cancers.

MANAGEMENT

The management of paraneoplastic syndromes includes the diagnosis of the syndromes, the associated antibody or antibodies, a malignancy workup, and, obviously, treatment. As the prognosis of these conditions many times depends on how quickly they've been treated, all the management arms should happen at the same time. Antibody panel results can take weeks to come back. Therefore, in the case of a suspicion of a paraneoplastic syndrome, it is better to start a treatment while the results are pending and the malignancy workup is running.

Due to the rarity of these disorders, there are no clinical trials or randomized studies, therefore all management recommendations are level C.

Diagnosis

Paraneoplastic syndromes should be suspected when acute/subacute neurologic symptoms arise. The investigation of paraneoplastic syndromes can use the same diagnostic armamentarium used in neurology. Figure 108.2 summarizes in an algorithm the necessary tests to be considered in the diagnosis of paraneoplastic disorders.

FIGURE 108.2 Algorithm for diagnosing paraneoplastic syndromes. Abbreviations: CAP CT, chest/abdomen/pelvis computed tomography; CSF, cerebrospinal fluid; EEG, electroencephalogram; ENMG, electroneuromyography; MRI, magnetic resonance imaging; PET-CT, positron emission tomography–computed tomography; US, ultrasound.

FIGURE 108.3 Anti-Hu encephalitis. A 60-year-old man presented with gradually worsening memory deficits and confusion, with subclinical seizures. Magnetic resonance imaging of the brain demonstrates T2/fluid-attenuated inversion recovery hyperintensity and mild expansion in the right medial temporal lobe *(white arrow)* **(A)**, right insular cortex (not shown), and left dorsal thalamus (not shown), without restricted diffusion (not shown) or postcontrast enhancement (not shown). The patient was in remission following treatment with intravenous immunoglobulin infusions, oral steroids, and chemotherapy, but he presented approximately 2.5 years later with worsening memory decline. Magnetic resonance imaging at that time **(B)** shows new T2/fluid-attenuated inversion recovery hyperintensity in the left medial temporal lobe *(white arrow)* with volume loss within the right medial temporal lobe *(white arrowhead)*. (Images courtesy of Dr. B. Griffith, Henry Ford Health System.)

Lumbar puncture is a resource that is commonly used because the majority of the patients will have alterations in the cerebral spinal fluid. The most common alteration is increased protein levels, but earlier in the disease, pleocytosis is more common. Increase in protein is seen in 67% to 92% of patients, oligoclonal bands in 30% to 77%, and pleocytosis in 28% to 88%.

Imaging studies are usually represented by MRIs, which are used to evaluate the neurologic symptoms LEVEL 3.[1] In limbic encephalitis, MRI of the brain can show alterations in the temporal lobes in 40% to 70% of patients (Fig. 108.3). Paraneoplastic myelitis is usually longitudinally extensive and symmetric. T2-weighted imaging is the most sensitive series, and enhancement can be seen using contrast. It usually affects the dorsolateral columns, but it can also affect the central gray matter.

Many diagnostic tests are used to look for the primary cancer. Computed tomography of the chest/abdomen/pelvis is usually the first to be performed LEVEL 3.[1] When computed tomography is negative, other exams can be added. In the case of NMDA and Ta antibodies, pelvic or test ultrasound should be considered LEVEL 3.[1] Another tool to be considered in any malignancy workup is whole-body positron emission tomography–CT LEVEL 3.[1]

Electroneuromyography is used to diagnose neuropathy, myopathy, or neuromuscular junction disorders LEVEL 3.[1] Unfortunately, it will not reveal whether the syndrome is paraneoplastic. Even muscle or nerve biopsies are unable to differentiate if a condition is paraneoplastic.

It is recommended to use a broad panel evaluating multiple antibodies rather than ordering individual antibodies LEVEL 3.[1] This is due to many reasons. A broad panel has a greater likelihood of identifying the causative antibody rather than one or two individual tests especially as antibodies can coexist, clinical manifestations may overlap, and one antibody can have multiple manifestations. Another reason is that with a broad panel, treatment can start after sample collection. A selective sequential algorithm of antibody testing would delay treatment and could result in false-negative results if antibodies were collected during or after starting immune therapy.

Treatment

Treatments are based on immune-modulator therapies and tumor removal LEVEL 3.[1] There are no clinical trials, and therefore, it is not possible to know which therapy is best. Acutely, the first line of treatment is usually with corticosteroids and/or immunoglobulin G (IgG) or plasma exchange. Second-line therapy is rituximab or cyclophosphamide. The most common doses are 1g of methylprednisone for 5 days for corticosteroids; 0.4 g/kg/d of IVIG for 5 days, five to seven sections of plasma exchange every other day, 375 mg/m^2 each week for rituximab. Long-term maintenance, when needed, is with mycophenolate mofetil, azathioprine, IVIG, cyclophosphamide, or rituximab infusions. In a noncontrolled trial of rituximab in patients with paraneoplastic

diseases associated with ANNA-1 and PCA-1 antibodies, 57% of patients improved.

Symptom management must also be addressed. In Lambert-Eaton disease, 3,4-diaminopyridine can be tried. In case of MG, pyridostigmine is the drug of choice. Benzodiazepines are used in stiff-person syndrome. Antiseizure medications are also used in paraneoplastic epilepsy.

Another question is how long should cancer screening continue for patients when a cancer is not found initially. One European task force suggested repeat oncologic workup every 6 months for 4 years, with the exception of LEMS in which screening efforts should be continued for 2 years.

OUTCOMES

The majority of paraneoplastic disorders have a good prognosis when treated quickly, and a delay in diagnosis has been associated with poor prognosis.

Prognosis is better with antibodies targeting cell surfaces such as calcium channels rather than intracellular targets.

Despite having favorable oncologic prognosis, patients with antibodies to Purkinje cells have poor neurologic prognosis, especially the PCA-1 antibody. Also, in paraneoplastic myelitis, the majority of patients will be either wheelchair dependent or need assistance with walking.

Complications of Cancer Therapy 109

Jasmin Jo and David Schiff

KEY POINTS

1. Neurologic complications from cancer therapy may diminish patients' quality of life. Early recognition and prompt management can improve symptoms and prevent permanent deficits.
2. Complications from radiation therapy are classified into acute (<1 mo), early-delayed (1-6 mo), and late-delayed reactions (>6 mo).
3. Chemotherapy-induced peripheral neuropathy is a major dose-limiting toxicity of chemotherapy.
4. Concomitant or sequential whole-brain radiation therapy with chemotherapy such as methotrexate may cause or increase the extent of leukoencephalopathy.
5. Neurotoxicity from immunotherapy results from immune activation leading to organ-specific autoimmune-like disease.
6. Cytokine-release syndrome and chimeric antigen receptor T-cell related encephalopathy can be life-threatening, and prompt and aggressive management is essential.

INTRODUCTION

Treatment for cancer may result in neurologic complications that can adversely affect patients' functional status and outcomes. Early recognition of the clinical manifestations can assist clinicians in timely diagnosis and management. In this chapter, we discuss common complications related to radiation therapy (RT), chemotherapy, biologic agents, and immunotherapy.

NEUROLOGIC COMPLICATIONS OF RADIOTHERAPY

Introduction

RT is one of the mainstays of treatment for primary and secondary central nervous system (CNS) tumors as well as for prophylaxis in certain systemic malignancies. Complications from RT are well recognized and can have debilitating effects on quality of life. The risk for radiation injury increases with higher total dose and fractions, larger treatment volume, and co-administration of chemotherapy. Patients younger than 10 and older than 70 years old are more susceptible to neurotoxicities from RT.

Pathobiology

Complications are typically categorized according to the temporal relationship to RT: acute (>1 mo), early-delayed (1-6 mo), and late-delayed reactions (>6 mo) (**Table 109.1**). The time differentiation is important because acute and early-delayed reactions are often reversible, whereas delayed complications are irreversible. Radiation-induced capillary injury with disruption of the blood-brain barrier (BBB) leading to edema is the mechanism during acute injury. Late injury is generally associated with permanent tissue damage. The proposed mechanism for late effects is a combination of vascular injury involving the small- and medium-sized vessels, demyelination with loss of oligodendrocytes, and immunologic response to antigens released from damaged glial cells. The pathologic end state is radiation necrosis, comprising of coagulation necrosis and gross demyelination. Tissue atrophy is seen on long-term follow-up.

TABLE 109.1 Neurologic Complications of Radiotherapy

			Clinical Syndromes According to Sites			
Type	**Onset**	**Pathology**	**Brain**	**Spinal Cord**	**Cranial Nerves**	**Peripheral Nerves**
Acute	<1 mo	BBB disruption Edema	Acute encephalopathy Pseudoprogression	...	...	Paresthesia
Early-delayed	1-6 mo	Edema Demyelination	Somnolence syndrome Transient cognitive impairment Pseudoprogression	Lhermitte sign	Painless visual loss Tongue weakness Hearing loss Anosmia	Transient plexopathy Pain
Late-delayed	>6 mo	Vascular injury Demyelination Necrosis Cellular loss	Focal radionecrosis Leukoencephalopathy Cognitive impairment Dementia	Brown-Sequard syndrome Spastic paraplegia	Hearing loss Visual loss Lower CN palsies	Irreversible plexopathy Myokymia on EMG

Abbreviations: BBB, blood-brain barrier; CN, cranial nerve; EMG, electromyography.

Clinical Manifestation, Epidemiology, and Diagnosis

Acute Encephalopathy

Acute encephalopathy can develop within a few hours to days after initiation of RT. This may occur when large doses per fraction (>3 Gy) are administered to a large treatment field, especially in patients with intracranial hypertension. Patients usually present with somnolence, headache, nausea, vomiting, and exacerbation of preexisting deficits. Increased in T2/ fluid-attenuated inversion recovery (FLAIR) hyperintense signal may be seen on magnetic resonance imaging (MRI) studies, although no specific neuroimaging findings are associated with acute injury. With better understanding of safe dose fractionation schedule, this complication is rarely encountered.

Pseudoprogression or Worsening of Preexisting Symptoms

This reaction may be seen acutely or subacutely, typically manifesting as worsening or reappearance of original neurologic symptoms, headache, nausea, and lethargy. Pseudoprogression refers to contrast enhancement within the tumor bed that usually mimics tumor progression. Advance imaging techniques using perfusion or positron emission tomography studies typically reveal diminished cerebral blood volume or hypometabolism, respectively. It occurs in at least 10% to 20% of patients with glioblastoma receiving concurrent RT and temozolomide; it manifests most commonly 1 to 3 months posttreatment, but it may occur later and usually improves within a few months.

Focal Radionecrosis

Cerebral radiation necrosis develops several months to years after external beam RT and after high-dose local radiation such as stereotactic radiosurgery. The risk of developing radiation necrosis increases with larger dose per fraction, higher total dose, and treatment volume. It is reported to occur in 5% to 24% of patients with brain metastases and up to 5% with primary brain tumors. Neurologic deficits depend on the location and size of radionecrosis. An MRI does not distinguish between radiation necrosis and tumor progression. Metabolic and perfusion imaging studies may help discriminate the two entities, but surgery remains the gold standard to confirm the diagnosis.

Leukoencephalopathy and Cognitive Impairment

Cognitive dysfunction frequently develops in 6 months to several years after RT, occurring in up to 90% of patients who survives more than 6 months after whole-brain radiation therapy (WBRT). Impairment can range from mild-to-moderate deficits in short-term memory and attention to dementia in about 12% of patients. Clinical syndrome resembling normal-pressure hydrocephalus (dementia, gait ataxia, and urinary incontinence) has been observed in radiation-induced leukoencephalopathy, which may improve with ventriculoperitoneal shunting. An MRI demonstrates T2/FLAIR hyperintense signal in periventricular white matter (leukoencephalopathy) and atrophy in nearly all cases. Concomitant or sequential chemotherapy with WBRT may increase the extent of leukoencephalopathy, such as in patients with primary CNS lymphoma who received methotrexate or cytarabine.

Radiation-Induced Myelopathy

Radiation-induced damage to the spinal cord is categorized into early-delayed (6 wk to 6 mo) and late-delayed (>6 mo) myelopathy. Acute worsening of neurologic deficits should prompt investigation for intratumoral hemorrhage or tumor progression. Early-delayed myelopathy is characterized by Lhermitte sign that typically resolves spontaneously without distinctive imaging finding. Patients with late-delayed myelopathy often presents with Brown-Sequard syndrome and spastic paraplegia with impaired sensory and autonomic functions. The condition may begin abruptly or insidiously and is most often irreversible. An MRI demonstrates T2/FLAIR hyperintensity and enhancement in the affected spinal cord levels early in the course, whereas spinal cord atrophy without signal abnormality can be seen years after the onset of the disease.

Cranial Neuropathies

Any cranial nerve may be involved if included in the radiation field. The hypoglossal nerve is the most vulnerable cranial nerve followed by the vagus nerve and the recurrent laryngeal nerve, believed to be due to absorption of higher amount of energy from RT to the neck region. Optic neuropathy, the most feared complication results in painless and progressive visual loss or visual field constriction. Thus, it is important to limit the radiation dose to the optic pathway. The oculomotor, trochlear, trigeminal, abducens, and facial nerves are less vulnerable and can be affected by focal RT for skull base tumors. Permanent damage to cranial nerves is rare and usually occurs due to delayed effect.

Brachial and Lumbosacral Plexopathies

RT-induced brachial and lumbosacral plexopathies may result from treatment of breast, lung, and pelvic cancers. The usual presentation includes paresthesia and hypesthesia, followed by weakness and amyotrophy. Pain is usually relatively mild and occurs late in the course, as opposed to severe pain in patients with malignant plexopathy. Myokymia seen on electromyography, hypointensity in T1- and T2-weighted sequences, and absence of mass on MRI suggest RT-induced plexopathy.

Indirect Radiation-Induced Complications to Nervous System

RT can indirectly cause endocrine dysfunction such as hypothalamic-pituitary impairment resulting in hypothyroidism, hypogonadism, hyperprolactinemia, and panhypopituitarism; vascular damage leading to stroke, hemorrhage, vascular malformations, and rarely, stroke-like migraine attacks after radiation therapy (SMART) syndrome; and secondary tumors such as meningioma, glioma, and sarcoma.

Management and Outcome

Corticosteroid (dexamethasone, intravenous [IV] or oral, 8-16 mg/d) generally reverses symptoms from acute and early-delayed injuries but has variable benefit in radiation necrosis. Anti–vascular endothelial growth factor agents such as bevacizumab (10 mg/kg every 2 wk or 7.5 mg/kg every 3 wk, IV) have demonstrated beneficial effects in patients with cerebral radiation necrosis. In rare occasions, surgical resection of cerebral radiation necrosis is indicated, providing both therapeutic and diagnostic benefits. The use of memantine at 20 mg/day within 3 days of initiating RT for 24 weeks results in delayed time to cognitive decline, reduced rate of decline in memory executive function, and processing speed in patients with brain

metastases receiving WBRT LEVEL 1.[1] The addition of hippocampal avoidance to WBRT with memantine reduced the risk of cognitive function failure by 26%, without differences in toxicity, intracranial progression free survival, and overall survival in patients with brain metastases LEVEL 1.[2] Boswellic acids, a phytotherapeutic agent obtained by extraction from *Boswellia serrata*, has been shown to reduce RT-induced cerebral edema in patients with primary or secondary malignant brain tumors in a small prospective study LEVEL 2.[3] Larger phase III studies are warranted to confirm this finding. Pain management and physical therapy are important aspects in the management of RT-induced plexopathy.

Recovery of symptoms is typically expected in acute and early-delayed RT injuries. However, delayed complications from RT are progressive and irreversible, leading to poor outcome and quality of life for long-term survivors.

NEUROLOGIC COMPLICATIONS OF CHEMOTHERAPY

Introduction

Cytotoxic chemotherapy can affect both the central and peripheral nervous system, with the latter being the most common site of toxicity (Table 109.2). The severity depends on the treatment dose, duration, route, existing co-morbidities, and coadministration of other neurotoxic agents. These toxicities can lead to dose reduction and cessation of treatment.

TABLE 109.2 Peripheral and Central Nervous System Toxicities From Cytotoxic and Targeted Agents

Clinical Syndromes	Agents
Acute and subacute encephalopathy	Ifosfamide, high-dose methotrexate, cytarabine, docetaxel, etoposide, 5-fluorouracil, paclitaxel, procarbazine
Aseptic meningitis	IT methotrexate, liposomal cytarabine (DepoCyt)
Cerebellar dysfunction	High-dose cytarabine (AraC), 5-fluorouracil (rare)
PRES	Cisplatin, cyclophosphamide, high-dose corticosteroids, L-asparaginase, gemcitabine, bevacizumab, sorafenib, growth factors, rituximab (rare); IT methotrexate and cytarabine
Chronic leukoencephalopathy	High-dose methotrexate, 5-fluorouracil, capecitabine, fludarabine, cladribine; IT methotrexate
Acute sensory dysesthesia	Oxaliplatin, ifosfamide, cytarabine (rare)
Chronic pure sensory neuropathy	Cisplatin, oxaliplatin, carboplatin, docetaxel, procarbazine, etoposide, bortezomib, thalidomide
Chronic sensory-motor neuropathy	Vincristine, vinorelbine, nelarabine, paclitaxel, ixabepilone, etoposide, fludarabine, 5-fluorouracil, procarbazine, bortezomib, thalidomide
Chronic autonomic neuropathy	Vincristine, thalidomide, ixabepilone (rare)
Vestibulocochlear toxicity	Cisplatin

Abbreviations: IT, intrathecal; PRES, posterior reversible encephalopathy syndrome.

Pathobiology

The mechanism of chemotherapy-induced peripheral neuropathy (CIPN), which refers to generalized, relatively symmetric injury to peripheral nerves, depends on the cytotoxic agents used. Antimitotic agents, such as vinca alkaloids and taxanes, disrupt microtubule-based axonal transport leading to length-dependent axonal injury. Platinum agents such as cisplatin cause neuropathy by apoptosis of sensory neurons in dorsal root ganglion. Transient alterations of voltage-gated sodium channels leading to altered nerve excitability and refractoriness may explain neurotoxicity from oxaliplatin. Despite the presence of the BBB, the CNS remains susceptible to neurotoxicity effects. Factors leading to increased vulnerability of CNS to neurotoxicity include disruption of BBB by direct effects of tumor or by RT, direct administration of drug into the cerebral spinal fluid (CSF) by lumbar puncture or Ommaya reservoir, and intra-arterial delivery of chemotherapy. Chemotherapy can also cause damage to neural progenitor cells responsible for neurogenesis and maintenance of white matter integrity causing leukoencephalopathy.

Clinical Manifestations, Epidemiology, and Diagnosis

Acute or Subacute Encephalopathy

Chemotherapy agents such as ifosfamide, high-dose methotrexate, and procarbazine can cause acute toxicities appearing during or few days after treatment, characterized by confusion, irritability, hallucination, personality changes, seizures, and drowsiness. Ifosfamide, a nitrogen mustard alkylating agent used in the treatment of lymphoma or sarcomas, might cause encephalopathy that occurs in up to 25% of treated patients, more frequent among patients with renal dysfunction. Brain MRIs may be unremarkable or demonstrate edema. Aseptic meningitis occurs in at least 10% of patients receiving intrathecal methotrexate or liposomal cytarabine, often encountered within 24 hours of drug administration. A CSF analysis reveals pleocytosis, elevated protein, and negative cultures.

Acute Cerebellar Syndrome

Acute cerebellar syndrome may develop in 10% to 20% of patients within several days after administration of high-dose cytarabine, a pyrimidine analog frequently used in the management of leukemias and lymphomas. The main risk factor for severe neurotoxicity is renal insufficiency. Older patients (older than age 50 years) and those with hepatic insufficiency may also be at higher risk. Initial manifestations include encephalopathy, confusion, lethargy, and seizures, followed by cerebellar signs such as truncal ataxia and gait instability; however, patients may develop diffuse symptoms without cerebellar signs. With time, MRI may demonstrate cerebellar atrophy due to loss of Purkinje cells.

Posterior Reversible Encephalopathy Syndrome

Posterior reversible encephalopathy syndrome (PRES), manifesting as acute or subacute onset of headache, seizures, confusion, and visual changes, has been reported from cisplatin, cyclophosphamide, high-dose corticosteroids, and gemcitabine. The MRIs typically show bilateral areas of abnormal T2/FLAIR signals, mainly in the parieto-occipital white matter, although involvement of anterior cerebral hemispheres, basal ganglia, thalamus, cerebellum, and/or brainstem have been reported.

Chronic Leukoencephalopathy

Chronic leukoencephalopathy, characterized by progressive personality change, dementia, ataxia, and incontinence, may occur months to years following methotrexate especially when given during or soon after WBRT. When radiation is given prior to methotrexate, the RT may disrupt the BBB and cause an increased permeability of the white matter to the methotrexate. Therefore, WBRT should be administered after systemic or intrathecal methotrexate. Diffuse white matter disease, cortical-subcortical atrophy, and ventricular dilation are typical imaging findings in chronic leukoencephalopathy.

Peripheral Neuropathy

A CIPN is estimated to occur in 30% to 40% of patients treated with chemotherapy, with incidence reported to be up to 60% in those who received cisplatin, paclitaxel, docetaxel, vincristine, and oxaliplatin. Patients typically present with symmetric distal paresthesia, loss of proprioception and vibratory sense, and loss of ankle reflexes. Distal motor weakness and autonomic dysfunction may also occur with certain agents, most prominently with vincristine. Vestibulocochlear toxicity is associated with cisplatin. Acute, cold-induced dysesthesia involving the distal extremities, throat, mouth, or face occur commonly with oxaliplatin. Nerve conduction studies in CIPN may demonstrate decreased sensory nerve action potential, prolonged latencies, and delayed conduction velocities. For classic presentations of CIPN, diagnostic testing is not usually required. Identification and treatment of coexisting conditions that cause peripheral neuropathy, such as diabetes, alcohol abuse, and vitamin B_{12} deficiency, is imperative in the management of CIPN. Paraneoplastic neuropathy, such as subacute sensory paraneoplastic neuropathy associated with anti-Hu antibodies should be distinguished from CIPN as treatment involves further cancer-directed treatment.

Management and Outcome

Acute CNS toxicities usually resolve within few days with supportive treatments. Methylene blue may be effective in treatment (50 mg IV 6 times per day) or prophylaxis (50 mg, IV or oral, 4 times per day) of ifosfamide-induced encephalopathy. Discontinuation of the offending agent is indicated if a patient experiences acute myelopathy or cerebellar syndromes. Cerebellar symptoms from high-dose cytarabine usually resolves within 5 days of discontinuing the drug, but approximately 30% of patients may have permanent neurologic deficits. There are no effective treatments for neurocognitive toxicities. Chronic leukoencephalopathy is often progressive and irreversible. Erythropoietin (40,000 U weekly), methylphenidate (10 mg twice daily), modafinil (200-400 mg/d), cholinesterase inhibitors such as donepezil (5-10 mg/d), nonsteroidal anti-inflammatory agents (ie, aspirin 100 mg daily), as well as cognitive rehabilitation have been studied but no definite recommendations can be made. The CIPN most often resolves on appropriate dose reduction or discontinuation of the offending agents. However, worsening of peripheral neuropathy ("coasting") may occur for a few months after cessation of treatment (eg, cisplatin, thalidomide), preventing timely discontinuation of treatment. Antiepileptic agents, tricyclic antidepressants, serotonin-norepinephrine reuptake inhibitor, opioids, and topical local anesthetics may provide symptomatic relief of CIPN (Table 109.3) LEVEL 2.[4] Neuroprotective agents have been used to prevent or limit neurotoxicity. However, calcium and magnesium infusion (1 g of each given immediately before and after each dose of oxaliplatin) did not substantially decrease oxaliplatin-induced sensory neurotoxicity in a phase III randomized controlled trial LEVEL 2.[5] Some nutritional supplements, such as acetyl-L-carnitine, may worsen rather than improve CIPN LEVEL 2.[6]

TABLE 109.3 Therapeutic Agents Commonly Used for Chemotherapy-Induced Peripheral Neuropathy

Agents	Dose
Carbamazepine	200 mg/d; target plasma level 4-6 mg/L
Gabapentin	100-2,700 mg/d
Pregabalin	75-150 mg/d
Lamotrigine	25-300 mg/d
Duloxetine	30-60 mg/d
Amitriptyline	50 mg/d
Morphine	10-15 mg every 4-5 h
Topical gel (BAK compound)	Twice daily

Abbreviation: BAK, baclofen (10 mg), amitriptyline (40 mg), ketamine (20 mg).

NEUROLOGIC COMPLICATIONS OF BIOLOGIC AGENTS

Monoclonal Antibodies

Rituximab, a humanized monoclonal antibody directed against CD20 antigen on the surface of B cells, which is frequently used in the treatment of B-cell malignancies, may cause headaches, myalgia, paresthesia, dizziness, PRES, and rarely progressive multifocal leukoencephalopathy. Bevacizumab, a humanized antibody against vascular endothelial growth factor, increases the risk of thromboembolic stroke and intracranial hemorrhage, may cause PRES, and rarely, optic neuropathy. Management of hypertension, appropriate supportive care, and in some cases discontinuation of the drug are recommended. Women with human epidermal growth factor receptor 2 (HER-2)–expressing breast cancer treated with trastuzumab, a humanized anti–human epidermal growth factor receptor 2 monoclonal antibody, may experience headache, dizziness, and insomnia after infusion.

Small Molecule Inhibitors

Small molecule protein kinase inhibitors target both membrane-bound and intracellular molecules and interfere with corresponding enzymatic activities. These agents in general have few neurologic complications as a class. Mild visual disturbance, including diplopia, photopsia, chromatopsia, blurred vision, impaired vision, and vitreous floaters, is seen in 45% of patients receiving crizotinib (anaplastic lymphoma kinase and c-Mesenchymal-epithelial transition factor inhibitor). Trametinib, a MEK inhibitor, also causes ocular toxicities such as blurred vision and chorioretinopathy. Muscle spasm is reported in 98% of patients treated with vismodegib (SMO inhibitor). Bortezomib, a proteasome inhibitor, causes length-dependent, painful, small-fiber sensory axonal neuropathy in 40% to 64% of patients with treatment-naïve multiple myeloma and is the most common reason for treatment discontinuation. Symptoms improve with discontinuation or dose reduction of the

offending agent. Carfilzomib, a second-generation proteasome inhibitor, has significantly lower incidence (14%) of neuropathy. Thalidomide, an immunomodulatory and antiangiogenic agent used to treat multiple myeloma causes peripheral neuropathy in 70% of patients presenting with sensorimotor axonal neuropathy and dysautonomia. The incidence and severity of peripheral neuropathy is significantly less from second-generation immunomodulatory agents such as lenalidomide and pomalidomide.

NEUROLOGIC COMPLICATIONS OF IMMUNOTHERAPY

Introduction, Epidemiology, and Pathobiology

Immunotherapy comprises both active therapies, such as antitumor vaccines, cellular-based therapies (chimeric antigen receptor T cells [CAR-T cells]), and pro-inflammatory cytokines (interferon and interleukin), and passive therapies in the form of monoclonal antibodies blocking immune checkpoints, including anti-cytotoxic T-lymphocyte associated protein 4 (ipilimumab) and anti-program cell death protein 1 (pembrolizumab and nivolumab). Patients on CAR-T cell therapy sometimes develop neurologic complications due to cytokine release syndrome, which occurs in up to 40% of patients. Interleukin-2 (IL-2) crosses the BBB, causing direct toxicity to the neurons and glial cells resulting in acute/subacute neurologic symptoms in 30% to 50% of patients who receive IL-2 in an IV bolus. This incidence is reduced by constant IL-2 infusion. Immune-mediated toxicities from check point inhibitors occur as a result of immune activation leading to organ-specific autoimmune-like disease. Mild-to-moderate neurotoxicities are encountered in about 10% of patients treated with immune checkpoint inhibitors (ICI), with severe, potentially life-threatening immune-mediated neurologic complications occurring in less than 1%.

Clinical Manifestations and Diagnosis

The ICI-related neurotoxicities range from involvement of the cortex to the muscles (Table 109.4). Encephalitis and meningitis are the best described CNS adverse effects to date; other reported complications include myelitis, encephalopathy, PRES, and exacerbation of multiple sclerosis. An MRI and a CSF analysis aid in the diagnosis. The majority of patients with acute and chronic immune demyelinating polyneuropathy present with sensory and motor symptoms, sometimes associated with dysautonomia and cranial neuropathies. Cytoalbuminologic dissociation on CSF analysis and evidence of demyelination on electrophysiologic studies are usually seen. Compared to patients with idiopathic Myasthenia gravis, ICI-related MG demonstrates a higher frequency of bulbar weakness and dyspnea on presentation. Cytokine release–associated encephalopathy manifest with delirium, aphasia, tremors, myoclonus, and seizures. Neuropsychiatric symptoms, most commonly depression, encephalopathy, hallucination, and seizures, are frequently reported with interferon-α. Transient encephalopathy and neurocognitive symptoms may develop toward the end of therapy with IL-2.

Management and Outcome

Early discontinuation of immunotherapy increases the chances of complete recovery. Steroids should be initiated first (methylprednisone 125 mg IV for 3 days followed by prednisolone 1 mg/kg/d) and often are sufficient to treat symptoms. Further immunosuppressive approaches (plasmapheresis for 3-5 sessions or IV immunoglobulin 2 g/kg given over 2-5 d) are indicated for refractory cases. Anticholinergic inhibitors for MG and empiric antibiotic or antiviral agents for encephalitis are also considered. Tocilizumab (4-8 mg/kg), a monoclonal antibody that binds to interleukin-6 receptors, and methylprednisolone (1-2 mg/kg every 12 h) have been used to manage

TABLE 109.4 Neurologic Toxicities From Immune Checkpoint Inhibitors

Clinical Syndromes	Incidence	Clinical Manifestations	Diagnosis
Encephalitis	0.1%-1%	Acute or subacute onset of confusion, fever, nuchal rigidity, or seizures	MRI: normal or with T2 hyperintensity in limbic structures and subcortical regions, dural thickening and meningeal enhancement; CSF: increased protein and WBC
Meningitis	0.1%-0.2%	Fever, nuchal rigidity, somnolence	MRI: meningeal enhancement; CSF: lymphocytic pleocytosis and negative cultures
Myelitis	NA	Subacute onset of weakness, numbness, gait disturbance, sphincter dysfunction	MRI: focal T2 hyperintensities CSF: pleocytosis
Cranial neuropathies	NA	CN VII and VI are commonly affected.	MRI to rule out other causes such as stroke or mass
Meningoradiculo-neuritis	NA	Headache, radicular pain, facial palsies, sensory deficit, flaccid weakness	Brain and spine MRI may be normal or show nerve roots enhancement.
AIDP	0.1%-2%	Rapidly progressive motor and sensory deficits, areflexia, facial palsy	EMG: slowed nerve conduction velocities, conduction blocks, and absent or prolonged F and H waves; CSF: cytoalbuminologic dissociation of mild pleocytosis and high protein
CIDP	NA	Length-dependent weakness and numbness, areflexia, autonomic dysfunction	Same as AIDP
Myasthenia gravis	0.1%-0.2%	Bulbar weakness and limb weakness; pure ocular symptoms are less common	Serology: positive AchR antibody; no reported cases of positive anti-MuSK; high CK; EMG: decrement on RNS and jitter on single-fiber test

Abbreviations: AchR, acetylcholine receptor; AIDP, acute inflammatory demyelinating polyneuropathy; CIDP, chronic inflammatory demyelinating polyneuropathy; CK, creatine kinase; CN, cranial nerve; CSF, cerebral spinal fluid; EMG, electromyography; MRI, magnetic resonance imaging; NA, not available; RNS, repetitive nerve stimulation; WBC, white blood cell.

cytokine release syndrome. Neurologic symptoms usually resolve after discontinuation of proinflammatory cytokines, although permanent dementia and persistent vegetative state have been reported.

NEUROLOGIC COMPLICATIONS OF HEMATOPOIETIC STEM CELL TRANSPLANTATION

Introduction and Epidemiology

Hematopoietic stem cell transplantation (HSCT) involves IV infusion of hematopoietic progenitor cells from the patient (autologous) or a human leukocyte antigen-matched donor (allogenic) to reestablish the bone marrow function destroyed by chemotherapy or chemoirradiation given to achieve myeloablation and eradicate cancer cells. Neurologic complications from HSCT are reported to occur in 11% to 59% of patients in clinical studies and in more than 90% in autopsy reports.

Pathobiology, Clinical Manifestations, and Diagnosis

Neurologic complications can be classified according to time of onset in relation to HSCT: (1) During stem cell harvesting and conditioning, neurotoxicities develop from myeloablative doses of chemotherapy. These include seizures associated with busulfan; encephalopathy with ifosfamide, melphalan, etoposide, thiotepa; neuropathy with carboplatin, cyclophosphamide, and etoposide; severe ototoxicity with carboplatin; and rarely, pain and myeloradicular syndrome after intrathecal methotrexate. (2) During bone marrow depletion, complications are due to organ failure resulting in metabolic abnormalities, coagulopathies, infections, and drug toxicities. Focal neurologic deficits should prompt neuroimaging studies such as computed tomography and/or MRI for suspicion of subdural and intraparenchymal hemorrhages as well as infection due to bacteria (*Staphylococcus* and gram-negative organisms), viruses (adenovirus, Coxsackievirus, herpesvirus, and cytomegalovirus), and fungi (*Candida* or *Aspergillus* species). (3) After bone marrow reconstitution, complications are secondary to chronic immunosuppression and graft-versus-host disease. About 5% to 8% of patients develop opportunistic CNS infection including toxoplasmosis, human herpesvirus-6, cytomegalovirus, John Cunningham virus reactivation, nocardia, and aspergillus. Major CNS complications from calcineurin inhibitors (cyclosporine and tacrolimus) include headache, altered mental status, seizures, cortical blindness, visual and auditory hallucinations, spasticity, paresis, and ataxia. The PRES is also reported, perhaps due to direct toxicity to vascular endothelium.

Management and Outcome

For patients with CNS infection, treatment is directed toward the inciting pathogens and should be empirically started if suspicion is high as microbiologic diagnosis is often difficult. Neurologic symptoms related to calcineurin inhibitors eventually resolve after reducing or stopping the treatment.

CONCLUSION

Neurologic complications can cause significant morbidity and mortality for patients treated for cancer. These complications can result from direct toxicity to the nervous system, indirectly through toxic-metabolic effects, or from immunosuppressant effects resulting in opportunistic infection. Early recognition and differentiation from metastatic disease or paraneoplastic syndromes are imperative for proper management as well as avoidance of inappropriate discontinuation or dose-reduction of therapeutic agents.

LEVEL 1 EVIDENCE

Hydrocephalus 110

Kumud Sharma and Fred Rincon

KEY POINTS

1. Hydrocephalus is characterized by an imbalance in the production, drainage, and reabsorption of cerebrospinal fluid (CSF) resulting in a dilation of the cerebral ventricles.
2. The only known cause of nonobstructive hydrocephalus is choroid plexus papilloma due to oversecretion of CSF.
3. Obstructive hydrocephalus is used to describe conditions that result near-complete blockage of CSF flow within the ventricular system.
4. *Communicating* hydrocephalus infers to CSF obstruction due to damage to the absorptive system after exiting the ventricles.
5. Normal-pressure hydrocephalus is a form of communicating hydrocephalus.

INTRODUCTION

The ventricular system of central nervous system is composed of two lateral ventricles: midline third ventricle and fourth ventricle. Ventricles and central spinal canal are lined by ependyma, which is a cuboidal epithelium. Choroid plexus, located in the floor of lateral, third, and fourth ventricles, are the main sites of cerebrospinal fluid (CSF) production. The epithelial cells of the choroid plexus secrete CSF. Choroid plexus are villous structures that project into the ventricles.

Hydrocephalus is characterized by an imbalance in the production, drainage, and reabsorption of CSF resulting in a dilation of the cerebral ventricles. The choroid plexus produces about 500 mL of CSF daily. The CSF circulates from the lateral ventricles to the third ventricle through the foramen of Monro. It then flows to the fourth ventricle via the cerebral aqueduct and exits into the subarachnoid space via the foramina of Magendie (medial) and Luschka (lateral) and moves into the subarachnoid space and spinal canal. The arachnoid villi granulations present within the superior sagittal sinus reabsorb the CSF into the venous system. At any given time, the total volume of CSF within the CNS is about 150 mL. The difference between production and quantity present is due to active absorption of CSF by arachnoid granulations.

CLASSIFICATION

Although various classifications of hydrocephalus have evolved historically, the several types are recognized (Table 110.1). Although all types of hydrocephalus are obstructive to some degree, the anatomic localization and severity of resistance to normal anterograde CSF flow can vary. *Obstructive hydrocephalus* is used to describe conditions that result to near complete blockage of CSF flow within the ventricular system. *Communicating hydrocephalus* describes conditions in which the ventricles are enlarged despite an open flow system from within the ventricles into the basal cisterns and over the convexities. Walter Dandy first described communicating hydrocephalus in 1914. He injected a tracer dye into one of the lateral ventricles. If the dye appeared in lumbar CSF, the hydrocephalus was termed *communicating*; if the dye did not appear in lumbar CSF, the hydrocephalus was termed *noncommunicating*. Because it proved useful in surgical-shunt placement, this functional classification was widely accepted. However, by this definition, *noncommunicating* hydrocephalus refers only to that caused by obstruction within the ventricular system. *Communicating* hydrocephalus infers CSF obstruction due to damage to the absorptive system after exiting the ventricles. Normal-pressure hydrocephalus (NPH) is a form of communicating hydrocephalus.

Hydrocephalus can be *acute* or *chronic*. Acute hydrocephalus can be an immediate threat to life when it develops rapidly over several hours and leads to intracranial hypertension and downward central herniation of the brain. By contrast, even massive ventriculomegaly can be minimally symptomatic if it develops gradually over weeks, months, or years and does not represent a threat to life.

Another classification of hydrocephalus is congenital versus acquired. Congenital hydrocephalus is present at birth. Acquired hydrocephalus can develop any time after birth. These forms of hydrocephalus are distinguished from *hydrocephalus ex vacuo* in which CSF volume increases without change in CSF pressure because of cerebral atrophy.

TABLE 110.1 Classification of Hydrocephalus

Obstructive hydrocephalus • Congenital malformations (ie, aqueductal stenosis) • Mass lesions causing ventricular obstruction (ie, acute intraventricular hemorrhage, third ventricular colloid cyst)
Communicating hydrocephalus • Defective reabsorption of CSF (ie, postinflammatory or posthemorrhagic) • Normal-pressure hydrocephalus • Venous insufficiency • Overproduction of CSF (ie, colloid plexus tumor) • External hydrocephalus (ie, preponderance of excess CSF over the convexities)
Hydrocephalus ex vacuo

Abbreviation: CSF, cerebrospinal fluid.

CEREBROSPINAL FLUID DIVERSION SYSTEMS

Shunt systems establish a connection between a CSF space (ventricular or lumbar) and a drainage cavity (peritoneum, pleural space, right atrium). The components of a CSF shunt include a proximal catheter, reservoir, valve, and distal catheter (Fig. 110.1). The proximal catheter is positioned intraventricularly, ideally away from choroid plexus (frontal horn of right ventricle is devoid of choroid plexus), and exits through a burr hole to connect with a reservoir in the subcutaneous tissue. The CSF may be sampled via this reservoir. A one-way valve regulates CSF flow into the distal catheter, which is subcutaneously tunneled to drain into a body cavity capable of reabsorbing fluid. All ventricular catheters are composed of silicone rubber and may vary in terms of length, internal/external diameter, shape, tip configuration, stiffness, and radiopaque markings. The valves now used include differential pressure regulators (static and programmable), flow regulators, siphon-resistive devices, and gravity-activated valves. The valves open or close based on a differential pressure, which is the pressure at the outlet (drainage cavity) minus the pressure at the inlet (intraventricular).

There are currently three different valve designs: slit, diaphragm, and spring-loaded ball-in-cone. The slit valve is an older design with a slit in the wall of the distal catheter, which opens with sufficient fluid pressure in the lumen of the catheter. The mechanical properties of the slit (silicone stiffness, wall thickness, length of slit) determine its operating pressure. Diaphragm valves have a flexible membrane, which moves in response to pressure differentials allowing CSF to flow around it. Finally, spring-loaded ball-in-cone valves contain a metallic coil or flat spring, which applies force to a ball located in a cone-shaped housing. When CSF pressure is high enough, the ball is pressed against the spring, which opens the valve. The CSF pressures change with posture (lying, sitting, or standing) and blood flow, which can alter shunt function. There are devices, which help prevent CSF siphoning during posture changes (standing up) by reacting to hydrostatic pressure across the two ends of the catheter and closing the valve. Gravitational devices use metal balls that fall into a cone-shaped seat upon standing, adding resistance to the flow in the shunt pathway equal to the height of a hydrostatic column. When the patient returns to a horizontal position, the balls move away from the fluid pathway, creating little resistance to the flow of CSF. Over drainage regulatory devices control CSF shunting during postural and vasogenic effects. Flow regulatory devices help maintain a continual flow through the valve at different pressures by varying the size of the valve opening and thus resistance to flow. Another treatment option for hydrocephalus is endoscopic fenestration.

ACUTE OBSTRUCTIVE HYDROCEPHALUS

Epidemiology

The global incidence of acute acquired obstructive hydrocephalus is unknown. Posthemorrhagic hydrocephalus occurs with an incidence of 25% to 70%, depending on the type and severity of the hemorrhage. Hydrocephalus is a frequently observed complication after recovering from aneurysmal subarachnoid hemorrhage (SAH). Despite a variable incidence of 6% to 67%, only 10% to 20% of SAH patients will require permanent CSF diversion. In pediatric populations, approximately 10% of infants with intraventricular hemorrhage (IVH) will require a shunt.

Pathobiology

In intraventricular obstructive hydrocephalus, the obstruction causes proximal dilation of the ventricles with preservation of normal ventricular size distally. Obstruction may occur at the foramen of Monro, the third ventricle, the aqueduct of Sylvius, the fourth ventricle, or the fourth ventricular outflow foramina of Luschka and Magendie. Obstructive hydrocephalus can be caused by congenital malformations, developmental lesions, mass lesions, or posthemorrhagic ventricular obstructions. According to Ayer, the ventricle closest to the obstruction enlarges

FIGURE 110.1 Cerebrospinal fluid (CSF) shunt system. **A:** Cranial segment with reservoir located behind the ear. **B:** Path of shunt tubing in the subcutaneous anterior, which ends in the peritoneal space. **C:** Cut-away view of shunt reservoir with one-way valve. Valve pictured is a Codman valve.

the most, for example, a mass in fourth ventricles leads to greater dilatation of the third compared to lateral ventricles.

Stroke and Intraventricular Hemorrhage

Ischemic stroke and intracerebral hemorrhage (ICH) complicated by IVH in adults also causes hydrocephalus (Fig. 110.2). In some patients, CSF flow obstruction is transient; therefore, intracranial pressure (ICP) increases and hydrocephalus appears but then disappears spontaneously. Other patients exhibit progressive hydrocephalus. Hydrocephalus also occurs in adults after SAH caused by head trauma or ruptured aneurysm (see Fig. 110.2). After SAH, distension of the arachnoid villi by packed red cells suggests an absorptive defect as a pathogenic mechanism for hydrocephalus.

In low birth weight infants, posthemorrhagic hydrocephalus is a major complication of IVH. Hydrocephalus results when a clot within the ventricular system obstructs CSF flow by a process of obliterative basilar arachnoiditis or by cortical arachnoiditis as a result of inflammatory response to blood products. There is an inherent predisposition to germinal matrix hemorrhage leading to periventricular hemorrhagic infarction and IVH causing hydrocephalus. Germinal matrix hemorrhage is graded by severity, as I through IV, whereby grades III and IV usually develop progressive hydrocephalus that requires shunting. Consequently, fibrotic impairment of extraventricular CSF pathways after IVH, SAH, or ICH may be complicated by dysfunction of arachnoid villi.

Tumor Related (Ball and Valve)

Intracranial neoplasms may cause obstructive hydrocephalus (Fig. 110.3). Tumors clustered about the third or fourth ventricles or the sylvian aqueduct, including pineal tumors, colloid cysts, gliomas, ependymoma, and metastases, are commonly implicated in intraventricular obstructive hydrocephalus. Prognosis, after shunting, is largely related to the type of tissue in the tumor. Other mass-like lesions, such as intraparenchymal cerebral hemorrhage, cerebellar infarction, or cerebellar hemorrhage, which assert local pressure on the ventricles, may lead to acute hydrocephalus. Basilar artery ectasia and other vascular abnormalities (eg, vein of Galen malformation) have also been associated with hydrocephalus.

Clinical Features

Patients with acute hydrocephalus clinically present with headache sometimes associated with visual obscurations, which could be followed by nausea/vomiting, subsequently leading to decreased mental status (stupor) and may lead to coma within minutes to hours depending on causation and availability of treatment. Corticospinal manifestations include lower extremity spasticity, increased deep tendon reflexes, and bilateral Babinski signs. It can progress to extensor posturing. The pupils are normal early in the process. Parinaud syndrome symptoms may appear as well. Roving eye movement, bilateral abducens palsy, and limitation of upward can be seen. If untreated, pupillary mydriasis will develop and roving eye movements will disappear. Depending on the speed of evolution, papilledema can be seen.

Diagnosis

In adults, the first test to be performed in suspected hydrocephalus is computed tomography (CT) or magnetic resonance imaging (MRI). Although CT can essentially exclude hydrocephalus, MRI is required for accurate assessment of subtle findings such as transependymal edema. The characteristic feature of hydrocephalus is ventricular enlargement out of proportion to sulcal

FIGURE 110.2 A 54-year-old man found unresponsive. **A:** He underwent endovascular coiling of a large left middle cerebral artery aneurysm and decompressive hemicraniectomy. **B:** The hydrocephalus persisted and he required a ventriculoperitoneal shunt after a restorative cranioplasty.

FIGURE 110.3 A,B: A 61-year-old female with a history of breast cancer presented with nausea and vomiting. She was found to have hydrocephalus secondary to brain metastasis as seen here in this T1 postcontrast magnetic resonance imaging.

enlargement. In general, brain atrophy due to degenerative disease or aging involves both "central" (ventricular) and "peripheral" (sulcal) spaces. But judging whether the ventricular enlargement is disproportionate can be difficult and is often fraught with interobserver disagreement. Thus, auxiliary features can be useful in assessing the likelihood of hydrocephalus. Abnormal periventricular white matter, with low attenuation by CT or increased T2-weighted or fluid-attenuated inversion recovery signal by MRI, suggests transependymal fluid flow, consistent with hydrocephalus, but periventricular white matter signal change is nonspecific and may arise from microvascular ischemic disease. Other allied structural changes suggesting hydrocephalus may include "ballooning" of the frontal horns of the ventricles, markedly dilated temporal horns, and bowing and thinning of the corpus callosum. Rapid longitudinal change can be diagnostically useful, but multiple CT or MRI studies over several years may not be available.

Confirmatory tests are often sought in hydrocephalus because of these uncertainties in clinical diagnosis and neuroimaging.

Treatment and Outcomes

The goal of treatment in hydrocephalic patients is to normalize CSF hydrodynamics. Treatment for every patient with hydrocephalus must be individualized. If the obstruction to flow is between the third and fourth ventricle, an endoscopic fenestration procedure can be attempted. In the case of a tumor obstructing CSF circulation, a surgical resection can be curative. If the cause of the alteration in CSF hydrodynamics is transient, the hydrocephalus may resolve during initial treatment, and temporary external ventricular drainage (EVD) or serial lumbar punctures (LPs) may be the only intervention needed. However, LP should only be employed in communicating hydrocephalus. In all forms of hydrocephalus, pharmacologic therapy is of limited value; however, there have been favorable reports of acetazolamide 500 mg orally three times a day as an adjunctive therapy to serial LP. Despite all this, most patients with symptomatic hydrocephalus will require CSF diversion through shunt insertion.

In adult-onset obstructive (noncommunicating) hydrocephalus, endoscopic third ventriculostomy (ETV) is an established treatment, with success rates of 60% to 80%. Its role in posthemorrhagic and postinflammatory hydrocephalus is debated. Common complications of this procedure include bleeding from injury to the basilar artery, intraventricular vessels, or brain parenchyma; infection; CSF leak; and hypothalamic injury. A large series published a mortality rate of 1% and permanent morbidity rate of 1.6% for ETV. Complications are more common with shunt procedures.

CONGENITAL OBSTRUCTIVE HYDROCEPHALUS

Epidemiology

Congenital hydrocephalus occurs with an incidence of 0.5 to 1.8 per 1,000 births per year and may result from either genetic or nongenetic causes.

Pathobiology

Common nongenetic causes include ICH and IVH secondary to birth trauma or prematurity and meningitis as a cause for congenital hydrocephalus. Meningitis and other inflammatory processes lead to blockage of CSF flow in the subarachnoid space especially around brainstem. This results in enlargement of entire ventricular system including fourth ventricle. Genetically, at least 43 mutants/loci linked to hereditary hydrocephalus

FIGURE 110.4 A 76-year-old man presented with 1-month history of gait dysfunction, memory loss, and urinary incontinence. **A, B, C,** and **D** are axial fluid-attenuated inversion recovery magnetic resonance images, and **E** is a sagittal T1 magnetic resonance image of chronic hydrocephalus secondary to aqueductal stenosis.

have been identified in animal models and humans. In some, aqueductal stenosis has been documented by MRI or at postmortem examination. It is not clear whether aqueductal lesions (eg, gliosis or fibrosis) occur developmentally or are the residue of prior viral inflammatory disease contracted in utero or in early life (Fig. 110.4). In some families, the occurrence of aqueductal stenosis, hydrocephalus of undetermined anatomic type, and the Dandy-Walker syndrome in siblings of both sexes suggests other modes of inheritance. In the Dandy-Walker syndrome, there is expansion of the fourth ventricle and the posterior fossa with obstruction of the foramina of Luschka and Magendie (Fig. 110.5). The Arnold-Chiari malformation may be associated with hydrocephalus at birth or it may develop later. Hydrocephalus could also result from congenital absence or decreased number of arachnoid villi.

FIGURE 110.5 Sagittal computed tomography scan showing a Dandy-Walker malformation.

Clinical Features

The manifestation of hydrocephalus is influenced by the patient's age. Infants will experience tension hydrocephalus if the insult occurs before the cranial sutures fuse at the end of the third year. This will cause skull enlargement and wide fontanels. If the hydrocephalus occurs recently after suture closure, it may be separated by the pressure (suture diastasis). The face will appear relatively small and with stretching of the skin of the scalp, prominent scalp veins appear. Upon percussion of the skull, a "cracked pot" sound is noted, known as *Macewen sign*. Scalp necrosis in these children can lead to CSF leakage and infections. Even mild increase in ICP molds infant's skull; radiograph of inner skull table reveals unevenly thinned appearance referred to as *beaten silver*. It leads to frontal prominence of the skull called *frontal bossing*. Head enlarges very rapidly surpassing 97th percentile. The anterior and posterior fontanels are tense. If left untreated, there is failure to thrive due to poor feeding and frequent vomiting. Parinaud syndrome eventually develops, which is caused by damage to midbrain tegmentum. The symptoms include paralysis or spasm of convergence, convergence-retraction nystagmus, visual loss and eventual optic atrophy, pseudo-Argyll Robertson pupils, eyelid retraction (Collier sign), and impaired upgaze or forced downgaze (setting-sun sign). Signs of corticospinal tract dysfunction include spasticity, increased deep tendon reflexes, positive Babinski sign, and wasting of trunk and limb muscles. The child will be developmentally delayed in motor and cognitive function.

Diagnosis

In infants, hydrocephalus must be distinguished from other forms of macrocephaly such as subdural hematoma. Sonography, described in Chapter 24, is useful in evaluating subependymal hemorrhage and IVH in high-risk premature infants and in following the infants for possible later development of progressive hydrocephalus (Fig. 110.6). Results correlate well with CT. As a bedside procedure, sonography requires minimal manipulation of critically ill infants. Plain skull radiographs and skull measurements are useful to follow the course of hydrocephalus in infants and children. Skull x-ray may also demonstrate erosion of the sella turcica or thinning of the inner table, "beaten silver cranium." Overall, CT and MRI are the best diagnostic aids for all forms of hydrocephalus. In X-linked hydrocephalus, laboratory testing for genetic analysis and counseling can be useful.

Treatment and Outcomes

Before CSF shunts were available 50 years ago, acute obstructive hydrocephalus used to be a lethal or severely disabling disease. If untreated, progressive infantile hydrocephalus carries a mortality rate as high as 50% at age 1 year and 75% at age 10 years. Treatment greatly improves these numbers. For example, with shunting, the survival rate is at least 50% after age 15 years but with a 15% incidence of mental retardation. If ICH leads to hydrocephalus in high-risk premature infants, the outcome is usually related to factors (eg, asphyxia) other than shunt responsiveness.

Endoscopic treatment of CSF pathway obstructions can effectively treat obstructive hydrocephalus, especially with aqueductal stenosis, and be used as an adjunct in treating loculated hydrocephalus. In ETV, a frontal region burr hole is made after a trajectory is chosen to provide a straight line linking the

FIGURE 110.6 This former 24-week premature infant suffered grade IV intraventricular hemorrhage and subsequent posthemorrhagic hydrocephalus. E and F are transcranial ultrasound images (coronal and sagittal, respectively) 1 week after birth.

foramen of Monro and the tuber cinereum, the space between the mammillary bodies posteriorly and the infundibulum of the pituitary gland anteriorly (Fig. 110.7). Stereotactic neuronavigation is commonly used for this. The endoscope is inserted and the foramen of Monro is first visualized in the lateral ventricle. The scope is advanced into the third ventricle and the tuber cinereum is identified. A probe is used to make a fenestration in the floor of the third ventricle and a balloon enlarges this hole. Endoscopic fenestration can also be performed prior to shunt insertion in cases where both foramen of Monro are obstructed. The procedure creates a connection through the septum pellucidum in these cases.

FIGURE 110.7 Endoscopic third ventriculostomy surgical approach.

COMMUNICATING HYDROCEPHALUS

When neither an intraventricular nor an extraventricular obstruction is documented, three other mechanisms may cause hydrocephalus: oversecretion of CSF, venous insufficiency, or impaired absorption of CSF by arachnoid villi. The absorptive capacity of the subarachnoid space is about 3 times the normal CSF formation rate of 0.35 mL/min (20 mL/h or 500 mL/d). Formation rates greater than 1.0 mL/min may produce hydrocephalus. Clinically, choroid plexus papilloma is the only known cause of oversecretion hydrocephalus. Absorptive capacity may be impaired in cases of inflammation in setting of infection or bleeding. Venous sinus thrombosis (especially superior sagittal sinus) leads to venous congestion and insufficiency thereby leading to decreased absorption of CSF into the venous system leading to hydrocephalus.

Among infectious diseases, bacterial, fungal, tubercular, or syphilitic meningitis may cause chronic hydrocephalus secondary to basal arachnoiditis (Fig. 110.8). Among parasitic infections, neurocysticercosis may produce both communicating and noncommunicating hydrocephalus. Otitic hydrocephalus occurs in children after chronic otitis media or mastoiditis with lateral sinus thrombosis. In these cases, the child may be febrile and listless. Eardrum perforation and purulent otic discharge usually occur. Often, ipsilateral sixth nerve paralysis and papilledema are noted. Otherwise, impaired cerebral venous drainage, for example, thrombosis of cortical veins or intracranial venous sinuses, rarely causes hydrocephalus.

Communicating hydrocephalus has been attributed to congenital agenesis of the arachnoid villi with consequent impairment of CSF absorption. Because detailed pathologic study of

FIGURE 110.8 A 47-year-old man with ventriculitis and secondary communicating hydrocephalus. A and B are postcontrast T1 magnetic resonance images. C and D are fluid-attenuated inversion recovery magnetic resonance images.

the number of villi and their structural characteristics is difficult and rarely performed, this defect may be more common than statistics indicate. Likewise, dysfunction of arachnoid villi without obstruction of basilar or transcortical CSF pathways is not easy to assess. Hydrocephalus has also been described when lumbar CSF protein content exceeds 500 mg/dL, as in polyneuritis or spinal cord tumor. The protein may interfere with CSF absorption. Ependymoma, the most common spinal cord tumor associated with hydrocephalus, may cause tumor seeding of the arachnoid villi.

Rarely, hydrocephalus due to impairment of extracranial venous drainage follows radical neck dissection or obstruction of the superior vena cava.

NORMAL-PRESSURE HYDROCEPHALUS

Epidemiology

Recent population-based studies have estimated the prevalence of NPH to be about 0.5% in those older than 65 years, with an incidence of about 5.5 patients per 100,000 per year. This is in accordance with comparable findings stating that although NPH occurs in both men and women of any age, it is found more often in the elderly population, with a peak onset generally in the sixth to seventh decades.

Pathobiology

The NPH is a form of chronic communicating hydrocephalus with incomplete obstruction of the normal pathway of CSF flow. The NPH most likely results from a serial pattern of increased resistance to normal CSF flow at the foramen of Monro, sylvian aqueduct, fourth ventricular outflow tracts, and the arachnoid granulations. The result is a relative increase in the volume of the lateral and third ventricles, with normal ICP. Symptoms are produced by stretching and secondary dysfunction and degeneration of white matter pathways in the corona radiata, which encase the lateral ventricles, and to a lesser extent white matter tracts in the internal capsule and below.

The NPH is often "idiopathic" and may relate simply to an abnormal brain aging process, whereas in some cases, it may follow SAH from trauma or aneurysm, a resolved acute meningitis or a chronic meningitis (eg, tubercular), tumor, or surgery or

nonprogressive meningeal and ependymal diseases. Irrespective of the underlying etiology, the ventricles expand at the expense of brain volume, causing both brain compression and periventricular white matter changes. These changes are thought to arise from brain edema caused by transependymal flow of fluid (Fig. 110.9) or to ischemic demyelination caused by compression of brain tissue. There may also be neuronal dysfunction from the compression. However, the overall effect is sufficiently chronic, or compensated, so that the CSF pressure is normal.

Clinical Manifestations

A different symptom complex is seen with NPH because the hydrocephalus in this disease process is slow and insidious. Patients present with a triad of gait ataxia, dementia, and urinary incontinence. Gait change is usually the first symptom, as well as the most frequent symptom, of NPH. This change may be subacute, fluctuating, or more chronic but most often worsens over weeks or months. The gait disturbance is often inconsistent and variable

FIGURE 110.9 **A-D:** An 85-year-old man presented with gait dysfunction and urinary incontinence for 3 months. His symptoms improved after a large-volume lumbar puncture. Axial fluid-attenuated inversion recovery magnetic resonance images of a patient with normal pressure hydrocephalus. Note periventricular transependymal interstitial edema.

but has parkinsonian features, with shuffling, shortened stride length, imbalance, and often initial slowness. Frequently, the gait is wide based (not commonly a feature of Parkinson disease), often with external rotation of the legs. The gait is classically described as "magnetic," with inability to lift the feet off the floor. It is also described as a gait "apraxia" because it appears that motor program involved in starting to move the legs is impaired, without evident impairment of strength. In addition to difficulty with the initiation of gait, there may also be difficulty maintaining gait, and there may be "freezing," with problems reinitiating movement. There is no rigidity, slowness of alternating movement, or tremor. Tremor is uncommon, but falls are common. Most commonly, it presents as unsteadiness and impairment of balance with greatest difficulty bring encountered at stairs and curbs.

Urinary symptoms are also frequent in NPH and may go unrecognized, consisting only of urinary urgency or frequency. Urinary incontinence itself is common, presumably due to loss of descending control mechanisms, with consequent unsuppressed bladder contractions, together with decreased voluntary ability to control the bladder outlet. A characteristic feature is said to be incontinence in which there is little evident concern regarding the problem.

Impaired cognition, ranging from subtle to severe, occurs in NPH, usually following after the onset of gait and urinary dysfunction. The characteristics of dementia associated with hydrocephalus include "subcortical" features. Symptoms may include not only forgetfulness but also slowness in mental processing, inertia, apathy, and impaired executive function, including decision making and task switching. Memory impairment in hydrocephalus may differ from that seen in cortical dementias such as Alzheimer disease (AD). As in AD, preservation of long-term knowledge can be seen, although the memory deficits more clearly involve poor learning. Impairment in delayed recall of learned material could relate to deficits in learning but may also involve initiation and speed of retrieval. For example, recall with simple cues may be much better than free recall, indicating a dominant deficit in retrieval rather than defective encoding of learned material. Advanced hydrocephalus results in severe slowing of mentation and possibly an akinetic mute state.

Diagnosis

When NPH is suspected, additional tests may be useful for diagnosis and to determine the likelihood of response to CSF shunting. An LP is indicated to measure CSF pressure and to determine whether it contains blood or signs of chronic inflammatory or infectious disease. The opening pressure on LP in NPH may be in the upper range of normal (14-20 cm H_2O), and such relatively higher "normal" pressures may also be indicative of a greater likelihood of benefit from CSF shunting. Continuous monitoring of intraventricular pressure may reveal higher pressures than lumbar CSF pressures. Either lumbar or intraventricular monitoring may reveal the presence of Lundberg B waves, mild transient ICP elevations (<10 min in duration and generally <20 mm Hg in amplitude).

Treatment and Outcomes

When patients are properly selected, CSF diversion or shunting is a safe and effective management of idiopathic NPH with a prolonged positive outcome LEVEL 2.[1] The response of the patient with suspected NPH to CSF diversion via a ventriculoperitoneal shunt (VPS) is best evaluated with a 48- to 72-hour trial

FIGURE 110.10 Suggested Algorithm for Diagnosis and Treatment of Normal-Pressure Hydrocephalus. Abbreviations: CSF, cerebrospinal fluid; fMRI, functional magnetic resonance imaging; NPH, normal-pressure hydrocephalus; PET, positron emission tomography; VPS, ventriculoperitoneal shunt.

of lumbar drainage (Fig. 110.10). This test, which requires hospital admission, essentially mimics the effect of a VPS, with the caveat that the CSF is drained out of the lumbar space (10 mL every 2 h) rather than the ventricular space. The main outcome measure of the test is subjective and objective observation of gait before, during, and after the procedure. Objective measurement is best made by videotaped recording of the patient prior to and at 24-hour intervals after the tap. In responders, gait typically improves during the first few days, with gradual loss of benefit over the next week after the lumbar drain has been removed. Cognition or urination may also improve, although this is usually less evident and more difficult to assess objectively. Lack of benefit from the tap points to likely lack of likelihood of benefit from CSF shunting. Response of symptoms to a single or

repeated large-volume (30-40 mL) LPs (the CSF "tap test") can also be attempted, but this test is not sensitive and may not detect improvement that can result from more sustained CSF diversion.

An alternative to VPS is lumboperitoneal shunting. A recent open-label randomized clinical trial (SIPHONI-2) demonstrated that lumboperitoneal shunting within 1 month of diagnosis may be beneficial in a selected cohort of NPH patients with similar long-term results as VPS LEVEL 1.[2] Radionuclide cisternogram to assess CSF flow in NPH, with a positive finding being delayed appearance of radiotracer in the lateral ventricles, does not appear to be prognostically useful for assessing the likely clinical response to VPS. An MRI evidence of an increased aqueductal CSF flow void, or an increased volume of CSF pulsing back and forth in the aqueduct ("aqueductal CSF stroke volume"), is similarly inconsistent and problematic as predictors of shunt-responsive NPH.

The decision which procedure is best for a patient should be individualized. In particular, treatment for NPH is neurosurgical and involves CSF diversion. The ETV is less likely to be a definitive management option for these patients. Shunting is most likely to be efficacious in those patients whose symptoms initially involved only gait and in those with milder cognitive dysfunction. It may also be more effective in those with a history of meningitis, SAH, or other identifiable "secondary" cause of hydrocephalus.

More successful outcomes are obtained in patients with positive spinal tap test; if the measured ICP is higher; an impaired cerebral blood flow reactivity to acetazolamide by single-photon emission computed tomography; and absence of comorbidities such as hypertension, peripheral vascular disease, stroke, and heart failure. Advanced age does not appear to be a significant predictor of poor response to shunting LEVEL 2.[1,3] No difference in outcomes after VPS placement has been observed when progressive reductions in valve opening pressures are used as compared to fixed settings LEVEL 3.[4] Patients with severe dementia, marked sulcal atrophy, or those whose first symptom is dementia, with subsequent gait and urinary involvement, are less likely to respond favorably to CSF shunting. This may relate to irreversibility of symptoms or perhaps a greater likelihood of underlying AD. Failure of shunting should be anticipated in patients with long-standing disease (dementia and incontinence) and/or who do not fit the typical syndrome of NPH. In some cases, lack of improvement can be explained by underdrainage and draining the ventricles at lower pressure can solve the problem.

LOW-PRESSURE HYDROCEPHALUS

Epidemiology

Low-pressure hydrocephalus is reported in the literature as case series, but no population statistics are known due to its uncommon occurrence.

Pathobiology

A clinical state has been described with low CSF pressures and acute symptomatic hydrocephalus in the setting of medium-pressure CSF diversion and ventriculomegaly, representing a paradoxical example of hydrocephalus with low ICP. Chronic shunting, SAH, IVH, and tumors have been associated with low-pressure hydrocephalus. It has been postulated that a decrease in cerebral elasticity coupled with the ventricular enlargement produces this syndrome. There are different viscoelastic theories that have been applied in attempts to delineate this physiologic occurrence.

Clinical Diagnosis

Pang and Altschuler (1994) described low-pressure hydrocephalus in great details. Their diagnostic criterion were (1) deterioration in neurologic status in presence of a medium pressure CSF diversion (either a shunt or EVD), (2) ventriculomegaly, (3) persistent ventriculomegaly with ICP in normal or low-normal range, (4) clinical and radiographic response to sub-zero drainage, and (5) exclusion of other causes like shunt or EVD malfunction.

Treatment and Outcome

Ultimately, this condition improves with subzero CSF drainage, which is achieved by setting the EVD height below the level of external auditory canal. These patients then eventually be treated with shunting with low pressure valves.

EXTERNAL HYDROCEPHALUS

External hydrocephalus presents as collections of subarachnoid fluid over the convexities, with or without coexisting ventriculomegaly. It can occur in both children and adults. In some cases, it can be difficult to determine whether the collection of fluid is truly in the subarachnoid or subdural space, and in some cases, both may exist. The criteria for diagnosis of benign external hydrocephalus in children is a rapidly enlarging head circumference along with a CT scan showing enlarged subarachnoid spaces, particularly in the frontal regions, and normal or only moderately enlarged ventricles. Kumar added absence of "clinicoradiological features of raised intracranial pressure," for example, ventriculomegaly without periventricular lucency and nontense fontanels as criterion for benign external hydrocephalus. The etiology in most cases is idiopathic, but it has been reported in many different conditions such as prematurity with IVH, SAH, meningitis, steroid therapy, chemotherapy, neurosurgery, and trauma. The most common theory suggests that external hydrocephalus is caused by immature arachnoid villi not being able to absorb the CSF that is produced continuously. The accumulated CSF then expands the ventricles and subarachnoid space within the compliant skull of an infant, thus avoiding marked increase in ICP. Arachnoid villi mature by age of 18 months. Why arachnoid villi are not mature in some infants is not entirely clear. Children with external hydrocephalus also have at least one close relative with macrocephaly in 40% of cases. An autosomal dominant mode of transmission is suspected. In adults, external hydrocephalus may be seen after trauma or SAH. Another cause is after surgical hemicraniectomy if the bone has not been replaced. It is important to differentiate adult external hydrocephalus from subdural hygromas because the latter will worsen if ventricular shunting is attempted.

GENERAL COMPLICATIONS AFTER SHUNT PLACEMENT

A shunt complication is any problem that requires repeat surgical intervention. This may occur due to mechanical failure causing improper device function, functional failure secondary to inadequate flow rate despite a working shunt system, or infection. The risk of shunt failure is highest in the first few months postoperatively, with a 25% to 40% failure rate at 1 year. The mean survival time for a shunt system is 5 years.

Complications can arise from any component of the shunt system. Shunt obstruction is the most frequent cause of mechanical failure in patients, with fracture of shunt tubing coming in second (Fig. 110.11). Occlusion can occur proximally at the ventricular catheter entry point, at the level of the valve, or at the end of the distal catheter. Proximal occlusions can be caused by CSF debris, a collapsed ventricle, or choroid plexus ingrowth. Proximal catheter blockage can be avoided by placing the catheter in the frontal horn of right ventricle, which lacks choroid plexus. Valve obstruction can be the consequence of debris accumulation,

FIGURE 110.11 Approach to suspected shunt malfunction. Abbreviations: CT, computed tomography; ICH, intracranial hemorrhage; ICP, intracranial pressure; OR, operating room.

bacterial proliferation, or the development of an immune reaction. Distal occlusion is most common in distal slit catheters due to accumulation of granulomatous nodules. Disconnection or fracture can occur at any fixation point, which causes tension along the catheter course or as a host reaction to foreign material causing degradation and calcification of the catheter. The functional complication of overdrainage occurs more frequently in the older adult population. Overdrainage may cause subdural hygromas or hematomas (due to stretching and rupture of bridging veins) or slit ventricle syndrome, a state of high ICP thought to be secondary to the CSF compartment decrease removing the buffer for volume change in blood or brain tissue. Problems such as migration, misplacement, skin problems, subcutaneous CSF effusions, pediatric craniostenosis, and ventricular loculation occur less frequently. Arachnoiditis and acquired tonsillar herniation are complications unique to lumboperitoneal shunts.

Infection remains an important and potentially devastating cause of shunt failure. Although intraoperative aseptic techniques and perioperative antibiotics have reduced the incidence of shunt infection, the infection rate is still reported as high as 5% to 10%. It can be divided by site of infection: meningitis, wound infection, peritonitis, or shunt equipment infection. Symptoms correlate to the site of infection. Most shunt infections occur within 2 months of surgery. In early postoperative infections, *Staphylococcus epidermidis* and *Staphylococcus aureus* are the most common organisms, but other bacteria related to skin flora such as *Propionibacterium acnes* also occur. Gram-negative bacteria are associated with late shunt infections. Treatment requires intravenous antibiotics; ceftriaxone plus vancomycin is an acceptable empiric treatment regimen. The infected hardware must be removed and EVD performed until infection clear. Ventriculoatrial shunts may cause bacterial endocarditis as an infectious complication.

111 Brain Edema and Increased Intracranial Pressure

Stephan A. Mayer

KEY POINTS

1. Brain edema can be classified as intracellular (cytotoxic and osmotic) or extracellular (vasogenic and interstitial).
2. Dexamethasone is useful for treating edema related to brain tumors and abscesses but has no role in the treatment of edema from stroke or trauma.
3. A stepwise tiered approach is the most effective way to treat elevated intracranial pressure (ICP).
4. Mannitol 20% at a dose of 0.5 to 1.5 g/kg or 23.4% hypertonic saline 0.5 to 2.0 mL/kg repeated as needed are the mainstay treatments for elevated ICP.
5. Decompressive hemicraniectomy is the definitive intervention for medically refractory ICP.
6. Acetazolamide 500 to 1,000 mg twice a day and if vision is threatened cerebrospinal fluid diversion are the primary treatments for idiopathic intracranial hypertension.

INTRODUCTION

Brain edema accompanies a wide variety of pathologic processes. It plays a major role in head injury, stroke, brain tumor, and cerebral infections such as brain abscess, encephalitis, and meningitis. Less common but equally devastating causes of brain edema include fulminant hepatic encephalopathy, hypertensive encephalopathy and posterior reversible encephalopathy syndrome (PRES), hydrocephalus, hypoxic-ischemic injury, hyponatremia, and other disorders associated with acute hypoosmolality (Table 111.1). Brain edema occurs in many different forms; clearly, it is not a single pathologic or clinical entity.

BRAIN EDEMA

Brain edema is defined as an increase in brain volume caused by an increase in water and sodium content. When well localized or mild in degree, brain edema is associated with little or no clinical evidence of brain dysfunction; however, when severe, it can cause massive intracranial mass effect and potentially fatal

brainstem herniation. Because the brain is encased in a rigid cranial vault, focal or generalized brain edema results in intracranial hypertension when it is severe enough to exceed the compensatory mechanisms that modulate intracranial pressure (ICP).

Brain tissue shifting or *herniation* results from the generation of compartmentalized mass effect and ICP gradients within the skull. The major forms of herniation are central, transtentorial (or uncal), subfalcine (or cingulate), and cerebellar (see Fig. 19.5).

Brain edema and vascular engorgement are different processes but can frequently coexist. *Brain engorgement* is an increase in the blood volume of the brain caused by obstruction of the cerebral veins and venous sinuses or by arterial vasodilatation, such as that caused by hypercapnia. Hypertension severe enough to overwhelm the brain's capacity to autoregulate and maintain a constant level of cerebral blood flow (CBF) is another common cause of brain engorgement. Brain engorgement is also known as *hyperemia* or *luxury perfusion*.

Pathobiology

Brain edema has conventionally been classified into three major categories: *vasogenic*, *cytotoxic*, and *interstitial*. The basic features of these three forms of cerebral edema are summarized in Table 111.2 with regard to pathogenesis, location and composition of the edema fluid, and changes in capillary permeability. A newer classification scheme focuses on the primary location of the edema fluid as *intracellular* or *extracellular*. In this scheme, the two main forms of intracellular edema are *cytotoxic* and *osmotic*, and the two main forms of extracellular edema are *vasogenic* and *interstitial* (hydrocephalic). Many causes of brain edema, including hemorrhagic stroke, venous infarction, and trauma, lead to a combination of these different forms of brain edema, and the varying contributions of each form of edema may change over time.

Vasogenic Edema

Vasogenic edema is a form of extracellular edema characterized by increased permeability of the blood-brain barrier to fluid, solutes, and macromolecules such as the plasma proteins, whose entry is normally limited by tight junctions between the capillary endothelial cells. The increase in permeability is visualized when contrast enhancement is observed with computed tomography (CT) or magnetic resonance imaging (MRI). Increased cerebrospinal fluid (CSF) protein levels are also indicative of increased endothelial permeability. MRI fluid-attenuated inversion recovery (FLAIR) sequences are more sensitive than CT for demonstrating the increases in brain tissue water content and extracellular volume that characterize vasogenic edema.

The biochemical basis of the changes in membrane integrity that underlie vasogenic edema involve the effects of free radicals (ie, superoxide ions, hydroxyl radicals, singlet oxygen, and nitric oxide) and polyunsaturated fatty acids, most notably arachidonic acid, in the peroxidation of membrane phospholipids. The ability of glucocorticoids to inhibit the release of arachidonic acid from cell membranes may explain their beneficial effects in vasogenic edema. By contrast, steroids such as dexamethasone have not been shown to be therapeutically useful in the treatment of cytotoxic or vasogenic brain edema associated with stroke or trauma.

Vasogenic edema is characteristic of clinical disorders in which a local tissue inflammatory response occurs when angiogenesis is stimulated by neoplasm, or when severe hypertension overwhelms the brain's capacity to autoregulate CBF. These disorders include brain tumor, abscess, hemorrhage, infarction with reperfusion, hypertensive encephalopathy, and traumatic contusion. Vasogenic edema related to varying degrees of vasodilation and blood-brain barrier disruption is also seen with acute demyelinating lesions in multiple sclerosis, hepatic or lead encephalopathy, Reye syndrome, and meningitis or encephalitis. Functional manifestations of vasogenic edema include focal neurologic deficits, focal electroencephalogram slowing, disturbances of consciousness, and intracranial hypertension. In patients with brain tumor, whether primary or metastatic, the clinical signs are often caused more by the surrounding edema than by the tumor mass itself.

TABLE 111.2 Classification of Brain Edema[a]

	Vasogenic	Cellular	Interstitial
Pathogenesis	Increased capillary permeability	Cellular swelling caused by energy failure or osmotic forces	Increased brain fluid due to block of CSF absorption
Location of edema	Primarily white matter	Gray and white matter	Periventricular white matter
Edema fluid composition	Plasma filtrate including plasma proteins	Increased intracellular water and sodium	CSF
Extracellular fluid volume	Increased	Early: decreased Late: increased	Increased
Capillary permeability to large molecules	Increased	Normal	Normal
Clinical disorders	Brain tumor, abscess, infarction (late), trauma, intracerebral hemorrhage, hepatic encephalopathy, high-altitude cerebral edema	Hypoxia-ischemia (early), hypo-osmolality (eg, hyponatremia), dialysis dysequilibrium syndrome	Obstructive hydrocephalus, idiopathic intracranial hypertension
Therapeutic Effects			
Steroids	Beneficial in brain tumor, abscess	Not effective	Not effective
Osmotherapy	Effectiveness limited by blood-brain barrier disruption	Effective	Rarely useful

Abbreviation: CSF, cerebrospinal fluid.
[a]Modified from Fishman RA. Brain edema. In: Fishman RA, ed. *Cerebrospinal Fluid in Diseases of the Nervous System*. 2nd ed. Philadelphia, PA: WB Saunders; 1992:116-137.

Cytotoxic Edema

Cytotoxic edema is a form of intracellular edema characterized by swelling of all the cellular elements of the brain (neurons, glia, and endothelial cells) with a concomitant reduction in the volume of the extracellular fluid space of the brain. Water accumulation related to cytotoxic edema tends to occur in three phases. In the first phase, the driving cause of cytotoxic edema is energy failure due to hypoxia, which results in adenosine triphosphate depletion and failure of active transport of sodium out of cells, resulting in intracellular sodium and water accumulation. Lactate and hydrogen ion accumulation also induces the entry of water into cells. The biologic basis of early cytotoxic brain edema, when cells are intact but metabolically challenged, involves astrocytic calcium signaling and activation of aquaporin-4 channels, which are the major influx route for water into the cell. Early in the course of cerebral ischemia, capillary permeability is usually not affected and tissue swelling is not evident.

Ionic edema is a newer term that describes a second stage in the course of cytotoxic edema due to hypoxia-ischemia. In this stage, while the blood-brain barrier remains structurally intact, additional sodium, chloride, and water accumulates within the extracellular space of the brain via upregulation of the Sur1-Trpm4 channel on the surface of endothelial cells. At this point, brain swelling begins to occur. Glyburide and other Sur1-Trom4 channel blockers targeting ionic edema formation are currently being tested in clinical trials of patients with middle cerebral artery infarction.

In the third stage of cytoxic brain edema, energy failure leads to cell death, complete disruption of cell membranes, and leakage of all intracellular contents into the extracellular space. In this final stage, tissue inflammation triggers disruption of the blood-brain barrier and the bulk flow of water, solutes, and plasma proteins into the infarcted tissue. As the process progresses to frank tissue infarction, vasogenic edema follows as the blood-brain barrier breaks down. The delay that occurs over several days in visualizing contrast enhancement with CT or magnetic resonance following an ischemic stroke illustrates that time is needed for defects in endothelial cell permeability to develop.

Osmotic Edema

Osmotic edema, like cytotoxic edema, is also caused by osmotic forces water shifting into cells but with the important difference that cellular energy failure does not play a role. Instead, the driving force is a sharp increase in the amount of free water in the extracellular fluid compartment, leading to an acute reduction in serum osmolality and movement of water into cells. Patients with pure cytotoxic edema have a normal CSF protein, and CT and MRI do not reveal contrast enhancement. As with cytotoxic edema, MRI diffusion-weighted imaging (DWI) reflects the restricted diffusion of water within swollen cells (see Chapter 22), but the process can be reversed with urgent but carefully controlled correction of the low serum osmolality.

There are several causes of osmotic edema, the most important being *acute hyponatremia* and the *osmotic dysequilibrium syndromes* that occur with hemodialysis (dialysis disequilibrium syndrome) and treatment for diabetic ketoacidosis. *Acute hyponatremia* and extracellular fluid can be caused by acute dilutional hyponatremia, syndrome of inappropriate secretion of antidiuretic hormone, or severe sodium depletion (see Chapter 125). The osmotic dysequilibrium syndromes that occur with hemodialysis or correction of diabetic ketoacidosis occur when excessive brain intracellular solutes result in excessive cellular hydration as elevated plasma osmolality is rapidly normalized. In the case of renal failure, the intracellular solutes presumably include a number of organic acids recovered in the dialysis bath. In diabetic ketoacidosis, the intracellular solutes include glucose and ketone bodies; however, there are also unidentified, osmotically active, intracellular solutes termed *idiogenic osmoles* that favor cellular swelling.

Major changes in cerebral function can result from processes that result in osmotic edema, including encephalopathy, stupor or coma, ICP elevation, brainstem herniation, asterixis, myoclonus, and focal or generalized seizures. As a general rule, intracellular edema caused by osmotic derangements is much more treatable than cytotoxic edema resulting from hypoxic-ischemic injury because cellular function remains viable. The extent of cellular swelling and neurologic dysfunction resulting from acute hypo-osmolality is directly related with how quickly it develops; chronic states of extreme hypo-osmolality that are reached gradually lead to minimal symptomatology.

Interstitial (Hydrocephalic) Edema

Interstitial edema is best characterized in obstructive hydrocephalus, in which the water and sodium content of the periventricular white matter increases because of the movement of CSF across the ventricular ependymal surface. Obstruction of the CSF outflow results in the transependymal movement of CSF and thereby an absolute increase in the volume of the extracellular fluid of the brain. Interstitial edema thus is strictly periventricular on CT and MRI, with predominance at the anterior and posterior aspects of the lateral ventricles. The composition of interstitial edema is similar to CSF. The clinical manifestations of interstitial edema (dementia, psychomotor slowing, and gait disorder) are often difficult to separate from those seen with normal pressure hydrocephalus in which there is physical traction on the periventricular white matter fiber tracts.

Selected Causes of Brain Edema

Cerebral Infarction

Most patients with arterial occlusion initially have cytotoxic edema followed by vasogenic edema, which are together termed *ischemic brain edema*. The cytotoxic phase takes place over minutes to hours and may initially be reversible. At this point, DWI may show dramatic changes well before evidence of completed tissue infarction can be demonstrated on MRI FLAIR sequences or by CT. Although osmotic or vasogenic edema can also be DWI positive, a phenomenon called *T2 shine through*, cytotoxic edema can be further differentiated from these causes on MRI because it is always associated with a reduction (low signal) in the apparent diffusion coefficient of water. The vasogenic phase of infarction takes place over hours to days as the tissue swells; in many cases, spontaneous vessel recanalization may occur and accelerate this process. A patchy and heterogenous pattern of contrast enhancement on CT or MRI at this point is characteristic.

Despite the theoretical concern that osmotic therapy with mannitol or hypertonic saline may aggravate tissue edema because these osmotically active substances may leak through disrupted endothelial cells into the infarcted brain tissue, clinical experience indicates that these treatments can effectively reverse the early stages of brainstem herniation. *Hemicraniectomy* is the definitive treatment of choice for younger patients (younger than 60 years) who are at risk for brainstem herniation due to complete infarction of the middle cerebral artery territory (see Chapter 36).

Intracerebral Hemorrhage

Perihematomal brain edema is a form of vasogenic edema that progressively increases over the first week after intracerebral hemorrhage (ICH; see Chapter 39). Symptomatic mass effect related to edema formation is the major cause of delayed neurologic deterioration after ICH. Perihematomal edema is caused by the local infiltration of plasma rich in thrombin and other coagulation proteins into the surrounding brain tissue. The thrombin then triggers a unique form of *neuro-hemo-inflammation*, stimulating the surrounding tissue to produce prostaglandins, complement, leukotrienes, and other inflammatory mediators that promote apoptotic cell death and blood-brain barrier disruption. Dexamethasone is not effective for treating perihematomal edema LEVEL 1.[1] A more recent trial of the iron chelator deferoxamine, directed at inhibiting iron-mediated inflammation, also failed to show benefit LEVEL 1.[2] A trial demonstrating worse outcomes in ICH patients on antiplatelet therapy treated with platelet transfusion suggests that inflammatory mediators included in the transfusion may aggravate perihematomal tissue injury LEVEL 1.[3]

By contrast, large doses of 20% mannitol (1.4 g/kg) have been shown to effectively reduce ICP and reverse clinical brainstem herniation in uncontrolled cohort studies. Insufficient local venous drainage, perhaps congenital or caused by local tissue compression and effacement, has been implicated in the pathogenesis of severe edema after ICH and might explain the benefits of bolus osmotherapy.

Subarachnoid Hemorrhage

Subarachnoid hemorrhage (SAH; see Chapter 40) can cause *global cerebral edema* that typically occurs at onset in poor-grade patients as well as a variety of forms of focal edema related to focal hematoma formation, cerebral infarction, brain retraction injury, and other causes. Global cerebral edema is considered the most important radiologic marker of *early brain injury* after SAH and initially is mostly vasogenic in nature (Fig. 111.1). The pathophysiology is thought to reflect transient hypoperfusion as a brief period of intracranial circulatory arrest associated with a massive surge in ICP, followed by reperfusion injury of the brain, with reflex hypertension in the setting of impaired autoregulation causing vascular engorgement. Global cerebral edema on CT affects 20% of patients and is associated with increased mortality and poor functional and cognitive outcome after SAH. Placement of an external ventricular drain is the first step in attaining ICP control; hypertonic saline and hypothermia are promising but untested potential interventions for mitigating further tissue damage.

FIGURE 111.1 Global cerebral edema in a patient with subarachnoid hemorrhage. Day 5: Computed tomography shows global swelling of the brain with effacement of the quadrigeminal cisterns. A focus of hemorrhage with surrounding edema is also evident in the left inferior frontal lobe. The patient was undergoing induced hypertension, which later was felt to be exacerbating brain edema. Day 14: Resolution of global cerebral edema is evident.

Venous Infarction

Venous infarction results from occlusion of the cerebral venous and dural sinuses usually in the setting of dural sinus thrombosis (see Chapter 41) or as a complication of a neurosurgical procedure. The result is tissue hypoperfusion with congestion and engorgement of the microcirculation, which results in a combination of cytotoxic and prominent vasogenic edema. Imaging shows extensive mass effect, patchy enhancement, and secondary hemorrhagic transformation of the infarct in most cases. In addition to standard measures to control ICP, treatment is directed at preventing clot propagation within the venous system with heparin anticoagulation. Interventional approaches to restore venous flow with local thrombolytic therapy can also be attempted as a heroic measure.

Cardiac Arrest

After cardiac arrest (see Chapter 38), massive swelling of the brain that develops over the next several days is an ominous sign. Patients are usually in deep coma, and recovery is rare. Standard measures to treat brain edema at that point are usually pointless because the extent of cellular necrosis throughout the brain is very severe.

Traumatic Brain Injury

Traumatic brain injury (TBI) can result in both focal and global brain edema (see Chapter 47). The global form of edema is largely vasogenic in nature and is felt to reflect neurogenic vascular engorgement and hyperemia in the setting of autoregulatory failure and dysfunction of vasomotor centers in the brainstem. In some cases, the patients present with a lucid interval after experiencing a concussion, followed an hour later by rapid progression to coma, as the brain massively swells. *Second impact syndrome* refers to rapid and catastrophic swelling of the brain that occurs when a person experiences a second concussion before symptoms of an earlier one have resolved. Standard measures to control ICP, with emphasis on hyperventilation and blood pressure (BP) control to reduce cerebral blood volume, are effective. Focal brain edema can result from contusional injury, brain compression from epidural or subdural hematoma, thrombin-mediated perihematomal edema, or cerebral infarction when brain herniation results in compression of the anterior or posterior cerebral arteries (see Chapter 47). Steroids are not effective, and in one study, high-dose intravenous (IV) methylprednisolone (Solu-Medrol) was shown to increase mortality, which was presumably due to immunosuppression, hyperglycemia, increased muscle catabolism, and impaired wound healing LEVEL 1.[4]

Brain Tumors

Brain neoplasms (see section XIV and Chapter 150) cause a pure form of vasogenic brain edema, which is caused by the local release of cytokines, angiogenic factors, and other proinflammatory proteins that result in blood-brain barrier disruption. Malignant and highly vascular tumors as a rule cause much more local

edema of the surrounding brain tissue than do benign neoplasms such as meningiomas, although exceptions can occur. The edema characteristically tracks along the white matter pathways on MRI or CT. Vasogenic edema associated with brain neoplasm is highly responsive to glucocorticoid therapy. In addition to standard measures to control ICP, *dexamethasone* is the treatment of choice; a typical starting dose is 4 to 10 mg every 6 hours. Bevacizumab, a vascular endothelial growth factor inhibitor, is an anticancer biologic agent, which can also be used in low doses (2.5-10 mg/kg IV every 2 wk) as a steroid-sparing option to treat severe tumor-related brain edema and radiation necrosis.

Fulminant Hepatic Encephalopathy

Acute fulminant liver failure from any cause can result in hepatic encephalopathy producing clouding of consciousness with prominent asterixis (see Chapter 124). As the severity of neurologic dysfunction progresses from lethargy to stupor to coma, massive swelling of the brain can occur resulting in dangerous elevations of ICP and brainstem herniation. The cause of the brain edema is poorly understood, and its onset can be unpredictable. Initially, the edema is primarily vasogenic with a large component of vascular engorgement. Ammonia and other substances normally metabolized by the liver cross the blood-brain barrier where they cause astrocytes to swell and disrupt endothelial tight junctions. Treatment relies on standard measures to control ICP; lactulose does not control brain edema when it is present. Optimal management requires placement of an ICP monitor after meticulous correction of the coagulopathy that usually is present. Transcranial Doppler sonography and jugular venous oxygen saturation monitoring demonstrate findings consistent with excessive hyperemia and can be used as end points to ensure that hyperventilation and BP control are not excessive. Mild to moderate hypothermia (33°C) has been shown to be effective in addition to more standard measures for controlling ICP, but liver transplantation is the only known definitive treatment. If the process is uncontrolled, herniation and brain death are a common outcome.

Reye Syndrome

Reye syndrome is a form of acute hepatitis with prominent fatty changes resulting from viral infection and exposure to aspirin that can occur in children. It is often accompanied by an encephalopathy characterized by progressive stupor and coma and a combination of cytotoxic and, to a lesser extent, vasogenic brain edema. Uncontrolled intracranial hypertension can lead to fatal brainstem herniation, and the pathogenesis is obscure. The disease is rarely seen today because of restrictions of the use of aspirin in pediatric patients.

Brain Abscess

Brain abscesses (see Chapter 65) caused by localized infection with bacteria, toxoplasmosis, cysticercosis, fungal infection, or other causes result in a pure form of vasogenic edema very similar to that produced by brain tumors. Local release of various inflammatory mediators results in increased vascular permeability. As is the case with neoplasms, the edema is highly responsive to dexamethasone 6 mg every 6 hours.

Viral Encephalitis

MRI DWI sequences in patients with viral encephalitis (see Chapter 69) reveal cytotoxic edema in the limbic cortex, including the medial temporal and inferior frontal lobes, insula, and cingulate gyrus without mass effect. In milder cases, FLAIR and CT may be negative, and the lesions are only apparent on DWI. In rare cases, viral encephalitis can result in a more fulminant pattern of generalized cytotoxic and vasogenic edema that requires ICP monitoring and treatment.

Meningitis

Severe generalized brain edema can occur with acute purulent bacterial or tuberculous meningitis (see Chapter 64). Such edema is caused by the inflammatory response generated by infiltrating polymorphonuclear white blood cells and has been termed *granulocytic brain edema*. Vasogenic edema predominates, but interstitial edema may also occur as the result of communicating hydrocephalus. Dexamethasone 10 mg every 6 hours for 4 days diminishes the inflammatory response and has been shown to improve survival and reduce cranial nerve injury in adults and children with bacterial meningitis regardless of whether brain edema is evident on imaging LEVEL 1.[5] A similar steroid regimen is also commonly used to reduce the inflammatory response in patients with tuberculous meningitis. Placement of an external ventricular drain may be required in cases with a significant component of hydrocephalus and is usually sufficient to control ICP.

Posterior Reversible Encephalopathy Syndrome

PRES is a clinical syndrome characterized by neurologic dysfunction and a characteristic pattern of brain edema that predominates in the white matter of the parietal and occipital lobes (Fig. 111.2). The edema is primarily vasogenic with cerebral perfusion pressure (CPP) breakthrough and disruption of the blood-brain barrier playing a large role in the pathogenesis of the disorder (see Chapter 44). FLAIR imaging is highly sensitive and often reveals scattered microbleeds on gradient echo (T2*) sequences. A wide variety of very different pathologic entities can cause PRES, including hypertensive encephalopathy resulting from poorly controlled essential hypertension, eclampsia, a variety of immunosuppressive agents, and end-stage renal disease (see Chapter 44). Clinical manifestations start with headache, confusion, visual disturbances (including cortical blindness in some cases), and seizures and can progress to stupor or coma. Massive swelling of the brain that requires ICP monitoring and therapy is unusual but can occur. Treatment is directed at removing any possible triggering agent and BP control with treatment

FIGURE 111.2 Posterior reversible encephalopathy syndrome. Fluid-attenuated inversion recovery images show abnormally increased signal *(arrows)* in the occipital and parietal white matter.

for seizures and elevated ICP as needed. Continuous infusion antihypertensive agents that allow precise BP control, such as labetalol and nicardipine, are preferred. Magnesium sulfate 4-g bolus followed by 10 to 12 g/h has been shown to improve outcome in women with eclampsia LEVEL 1.[6]

High-Altitude Cerebral Edema

This condition is a form of global and purely vasogenic cerebral edema caused by excessive cerebral vasodilation triggered by hypoxia in high altitudes. In addition to vascular engorgement, endothelial disruption results in fluid leakage into the brain. The condition can be rapidly fatal. MRI shows posterior white matter edema with a predilection for the splenium of the corpus callosum. Immediate descent (600-1,200 m), acetazolamide 500 mg every 6 hours, and delivery of supplemental oxygen are the treatments of choice.

Postendarterectomy Hyperperfusion Syndrome

This unusual complication of carotid endarterectomy or stenting occurs in patients who have long-standing high-grade carotid stenosis. Immediately after revascularization, the cerebral circulation remains maximally dilated and is unable to recover the capacity to autoregulate. The result is a pulsatile headache; more severe cases involve focal neurologic defects related to vasogenic edema in the downstream anterior circulation. In some cases, hemorrhagic conversion occurs. Meticulous BP control can minimize the extent of injury, and the syndrome typically resolves over several days.

FIGURE 111.3 Decompressive hemicraniectomy in a 58-year-old man with left putamen intracerebral hemorrhage. On day 3, he experienced brainstem herniation with bilateral motor posturing and a fixed and dilated left pupil despite aggressive medical intervention. He underwent urgent hemicraniectomy and duraplasty with restoration of midline positioning of the brain evident on day 11. The day 29 image shows normalization of brain morphology after replacement of the bone flap. The patient made a near-complete recovery.

Intracranial Pressure Management

General Approach

As outlined earlier, the optimal therapy of brain edema depends on the cause. A patent airway, maintenance of an adequate BP, and the avoidance of hypoxia are fundamental requirements in the care of these patients. The administration of appropriate parenteral fluids to meet the needs of patients is also essential. Administration of salt-free hypotonic fluids to patients with cerebral edema should be strictly avoided because serum hypo-osmolality increases brain swelling. As a general rule, inflammatory processes that predominantly involve vasogenic edema respond to dexamethasone (with the exception of vasogenic edema in patients with stroke or trauma) and measures to minimize brain engorgement and cerebral blood volume, including tight BP control and hyperventilation. By contrast, cytotoxic or cellular edema resulting from fluid and solute overload on the intracellular compartment responds best to osmotic therapy.

Neurosurgical decompression of the cranial vault can be lifesaving and should always be the *first and last* consideration when patients are at risk for secondary deterioration due to compartmentalized intracranial mass effect. Surgical options include placement of an external ventricular or lumbar drain for drainage, craniotomy to remove an intracranial mass lesion, or, as a last resort, hemicraniectomy with duraplasty to definitively decompress the cranial vault (Fig. 111.3). In all comatose patients where (1) intracranial hypertension elevation is suspected, (2) imaging shows mass effect due to brain edema, and (3) aggressive intensive care unit care is indicated, placement of an ICP monitor is essential. Empiric treatment of suspected ICP should be performed in the short term but only when ICP and CPP are actually being measured can the problem be optimally treated.

Tiered Approach to Intracranial Pressure Management in a Monitored Patient
